Enhanced knowledge of the coupled hydrologic, geochemical, and microbial processes controlling radionuclide migration in soils will improve our conceptual understanding and predictive capability of the risks associated with spread of radioactive material in the subsurface environment. Too often risk assessment models treat soil and bedrock as inert media or assume that the media is in equilibrium with migrating contaminants. Failure to consider the time-dependent coupled processes that control radionuclide migration will greatly overpredict the off-site contribution of contaminants from the primary waste source and thus provide an inaccurate assessment of pending risk. By recognizing the importance of soil processes on radionuclide migration, we can improve our decision-making strategies regarding the selection of effective remedial actions and improve our interpretation of monitoring results after remediation is complete.

Raindrop Impact and Splash Erosion

Hossein Ghadiri

*School of Australian Environmental Studies, Griffith University, Nathan Campus,
Nathan, Queensland, Australia*

Abstract

The highest amount of splash loss occurs when the soil surface is at or just above saturation. Any degree of suction to soil water or depth of water on the surface reduces the splash loss. Surface slope only affects the distribution of splash particles with a greater proportion moving downslope as the slope angle increases. Release velocity and trajectory of splash droplets are dependent on the angle and velocity of splash corona. Crater size and shape are dependent upon both drop and surface characteristics. Craters formed in water or saturated soil pastes are hemispherical but shallow with a raised center in compacted soil and sand. Crater volume, which is a more accurate measure of total soil loss by the impacting drop, can be predicted using impact impulse and surface shear strength.

INTRODUCTION

The first comprehensive study of splash erosion and the mechanical action of falling raindrops on soils was carried out in 1940s.^[1–3] The recognition of the importance of raindrop splash in water erosion was a breakthrough which opened a new chapter in soil erosion research and resulted in the development of erosion prediction models such as Universal Soil Loss Equation (USLE),^[4] European Soil Erosion Model (EUROSEM),^[5] and Revised USLE (RUSLE),^[6] in which rain erosivity is expressed in terms of rainfall energy. However, after this big leap forward, research into the mechanics of raindrop impact and soil splash stagnated for nearly 40 years. Ellison's^[2] assumption of rainfall energy being the driving force of water erosion remained unchallenged and adopted by almost all the researchers and modelers in the field. The main reason for the lack of further progress in the study of raindrop impact during this period was the multitude and complexity of the processes that take place in a very short period of time following raindrop impact and the elaborate facilities such studies required.^[7] It was only after the application in erosion studies of high-speed photography technique, which was capable of slowing down the fast processes of impact and splash by several thousand times, that some of these complex processes began to be observed and explained.^[8]

Photographic studies of raindrop impact erosion of the 1970s and 1980s identified three main processes that take place concurrently or in quick succession following raindrop impact.^[8–10] They have been named as “impact,” “splash,” and “cratering” processes. Impact and splash processes have since been studied by many researchers,^[11–13] but “cratering” has not received much attention in soil erosion studies. On the other hand, cratering is the only aspect

of water drop erosion which researchers in the aerospace and turbine industries are concerned with.^[8,14,15] These three processes are discussed individually.

RAINDROP IMPACT

The studies of water drop impact on solid and liquid surfaces started as early as 1876.^[16] Simulating the conditions inside turbines revealed that water drops at very high speeds can cut through even the hardest metals, and the damage increases rapidly by some power of impact velocity.^[14–16] As the impact damage can be caused both by direct impact pressure and by the lateral outflow of drop water, the impact process is subdivided into “impact pressure” and “lateral flow stress.”

Impact Pressure

Early studies of the impact of liquid drops on solid surfaces have shown that high pressure develops under the impacting drop as a result of a process known as “water hammer effect.”^[15,17,18] The water hammer pressure “P” develops when the front end of a moving water drop is stopped instantaneously and lateral flow is prevented; thus, compressive pressure builds up. The general form of the water hammer equation is as follows.

$$P = \rho VC \quad (1)$$

where ρ is the liquid density, C is the velocity of sound in water, and V is the impact velocity.

The duration of the compressible phase of impact is extremely short, but its existence has been reported by several researchers.^[8,10,11,19] The measurement of impact pressure and its distribution over the contact area for free

falling water drops has been attempted using miniature pressure transducer and nylon mesh penetration techniques.^[8,10,11,19] A concentration of transient compressive stress around the periphery of the impact area with a magnitude several times higher than the average impact pressure and a duration of about 50 μ s has been reported.^[8] The measured pressure inside the high-pressure ring is comparable in value with the calculated water hammer pressure under similar conditions.^[8,19] The duration and the effective area of this pressure are so small that they cannot have any lasting effect on soil surface. However, the propagation of shock waves into soil aggregates may cause lines of weakness and promote their early collapse under subsequent impacts.

Stress Associated with Lateral Flow

Lateral flow of drop water follows the short compressive period of impact. This flow is several times faster than that of impact velocity.^[19,20] Lateral flow slows down to about impact velocity in less than 1 m and turns into a corona that expands both vertically and horizontally. The shear stress associated with the initial high-speed lateral flow is very high and operates on a circle just outside the impact area.^[8] Such a high shear stress could cause damage to the surface and remove some soil material no matter how small the drops or stable the aggregates are. There are, therefore, two possible causes for the existence of a high-pressure ring around the periphery of the impact area, a short-lived compressive impact, and the shear stress associated with lateral flow.^[8,19]

SPLASH

Formation and Characteristics of Splash Corona

Initial sideways flow and the early stages of splash corona appear to be made entirely from drop water. Surface water and material join in later when the third process, cratering, begins digging into the surface.

Sideways flow of the impacting drop soon turns into a splash corona, which continues to expand laterally and grow vertically. The characteristics of splash corona are affected mainly by the presence or absence of a water film on the surface and surface roughness.^[20] Splash on an unsaturated compacted soil produces a corona with a small angle with the surface and a short life. When the surface material is loose enough to be set in motion by the impacting drop (i.e., saturated soil paste), the angle of the splash corona increases, and as the surface material joins in, the corona gets larger and taller before breaking up into droplets (Fig. 1). With a water film on the surface, corona walls become almost vertical and splash duration increases significantly (Fig. 2). Splash corona on a

Fig. 1 Splash caused by a 5-mm water drop falling at its terminal velocity on a saturated soil paste.

bed of saturated stable aggregates or sand particles is discontinuous, consisting of a number of tall discrete jets formed when flow is intercepted by large particles.^[20]

Splash Droplets

Splash droplets start forming almost immediately after the lateral flow of the water drop begins, but the early droplets are very small and, because of their trajectory and size, cannot travel far. Splash droplets grow in size with the elapse time after impact. They get larger as the surface water and material join in to make the corona wall thicker and flow within the wall slower (Fig. 1).^[10,20]

The mechanism of the breakup of the top of the corona into jets and jets into droplets has received some attention but has not been fully studied.^[21] It has been established that a cylinder of water becomes unstable when its length exceeds its perimeter, and oscillation and surface tension cause segmentation of the jet with the length of each

Fig. 2 Splash caused by a 5-mm water drop falling at its terminal velocity on a soil surface covered with a 5-mm water film.

segment depending on the velocity and the thickness of the jet. The breakup of the jets into droplets and the variation with time of the size and velocity of droplets are not affected by the presence or absence of soil material in the jets or in droplets. If soil particles are big and stable, they will be lifted toward the end of the splash when droplets are big enough to carry large particles. In other words, unless the duration of splash is long enough for the formation of droplets as big or bigger than soil particles, the lift up of these particles will not take place.^[8] The prolongation of splash duration is mainly associated with the presence of surface water and, to a lesser extent, with raindrop size. The smaller the target particles, intrinsically or following breakdown under impact, the earlier is their removal by splash and the faster and further they travel (Fig. 1). When soil surface is not covered with a thick water film, almost all the splashed droplets carry some soil material regardless of how stable the aggregates are.^[8,20,22]

The number and distribution of splash droplets are affected by the condition of soil surface, in particular the presence and the thickness of a water film on the soil surface and the size and velocity of the impacting drop. A 5-mm drop impacting at terminal velocity on a saturated

soil produces about 5000 splash droplets. The number decreases to about 1200 for a 2-mm drop.^[8,20] Others have reported lower numbers of splash droplets,^[23] possibly because of the inability of their techniques to capture and record very small droplets formed during the early stages of splash.^[22,24]

Loss of Soil Material by Splash

Between 15% and 25% of impact energy is used up in splashing water and soil material. The relationship between splash loss and kinetic energy is close but non-linear. The same relationship exists between soil shear strength and splash loss.^[25–28] Impact impulse appears to have a better and more linear relationship with splash loss, which suggests that an erosivity index based on impact force or stress may be more valid than the more popular energy-based index.^[8]

Splash loss appears to be dependent on surface water status and soil particle size. It has been said that a water film of depth of up to one-drop diameter increases the effectiveness of impact and increases the loss of underlying material. However, a detailed study carried out by Ghadri^[8] showed that the presence of a water film of any thickness cushions the impact and reduces its effectiveness in dislodging and splashing of surface material. It also reduces the traveling distance of splash droplets by making the corona walls vertical and the angle of splash close to 90° (Fig 2). Thus, the only effect that a water film, of any thickness, can have on splash is to reduce the splash loss of underlying material. Soil water tension also reduces the splash loss by making the splash duration shorter. Splash loss of surface material is, therefore, at its maximum when the soil is at or just above saturation (Fig. 3).

Total splash, water plus solid particles, increases with the depth of surface water up to about one-drop thickness. If, therefore, the first impact brings target particles into suspension to be splashed out by a subsequent impact, this may result in an increase in material loss with the presence of a thin film of water on the surface.

Slope steepness appears to have little effect on the total amount of material lost through splash, thus making splash

Fig. 3 Effect of surface water condition on the loss of soil material by rain splash.

loss a factor of the actual impact velocity rather than its normal component. The main effect of slope is on the distribution of splash material up and down the slope and their traveling distances.^[8,20] The following relationship has been suggested by Ghadiri^[8] between percent slope (S) and the downslope moving fraction of splash material (D)

$$D = 56 + S \quad (2)$$

CRATERING

During the first few microseconds of impact, all surfaces, including water, behave like a solid and have no involvement in the lateral flow of drop water.^[8,10,24,29,30] Once the surface water or material is set in motion, a crater begins to form and a splash corona starts to rise tangent to the crater sides. A crater formed in deep water soon obtains a hemispherical shape, with its depth and diameter steadily increasing to a maximum, to be followed by its collapse and the formation of a tall Raleigh jet.^[21]

Impact on different surfaces produces craters of different shapes and sizes, ranging from circular depressions on compacted sand and soil under suction to almost completely hemispherical shapes on the saturated soil pastes. One of the features of the craters formed on most soils is the formation of a relatively large rim around its edges due to the deposition of slow moving splash material toward the end of the cratering process. This rim makes up the bulk of the large difference between crater volume and the volume of splashed material. Rim material can become a part of the erosion loss if rainfall is followed by runoff or if the soil is on a steep slope where rim materials are prone to mobilization. Crater volume, therefore, may be a better indicator of raindrop's capacity to dislodge soil material than the amount of soil splashed out.

Between 10% and 20% of impact energy is spent in cratering, and both low and high-speed impact studies have reported direct, but curvilinear relationships between impact energy and crater volume.^[30,31] The following empirical equation has been developed between crater volume (V), impact energy (E_k), and target shear strength (σ) for high-speed impacts:^[31]

$$V = E_k / 4\sigma \quad (3)$$

where E_k/V was later shown to be dependent on drop size and impact velocity. E_k was later replaced with impact impulse (I) as I/V proved to be independent of drop size and velocity.^[8] The following equation was then developed between crater volume (V), impact impulse (I), and soil strength, the latter represented by the depth of cone penetration (P) of Hansbo's^[32] fall cone penetrometer:^[8]

$$V = kI P^2 \quad (4)$$

where k is a proportionality constant.

CONCLUSION

Impact impulse and surface shear strength appear to be the main drop and soil factors involved in all three processes of impact, splash, and cratering. As impulse is a product of impact force and its duration, it is possible that the entire prerunoff process of rain erosion is driven by impact force and its duration. This would account for the disproportionately higher erosivity of larger raindrops. The existence of a zone of transient high pressure around the peripheries of the impacting drops, caused by the compressive deformation of the drop (water hammer) or by the high-speed lateral flow, is established, but its significance in the breakdown of soil aggregates or their weakening by the shock waves generated under impact is not fully understood.

The highest amount of splash loss occurs when the soil surface is at or just above saturation. Any degree of suction to soil water or depth of water on the surface reduces the splash loss. Surface slope only affects the distribution of splash particles with a greater proportion moving downslope as the slope angle increases. Release velocity and trajectory of splash droplets are dependent on the angle and velocity of splash corona. Crater size and shape are dependent on both drop and surface characteristics. Craters formed in water or saturated soil pastes are hemispherical but shallow with a raised center in compacted soil and sand. Crater volume, which is a more accurate measure of total soil loss by the impacting drop, can be predicted using impact impulse and surface shear strength.

Rapid Soil Analysis: Diffuse Reflectance Spectroscopy

Keith D. Shepherd

World Agroforestry Center, International Centre for Research in Agroforestry (ICRAF), Nairobi, Kenya

Markus G. Walsh

World Agroforestry Centre (ICRAF), Kisumu, Kenya

Abstract

Diffuse reflectance spectroscopy (DRS) is a technology for non-destructive characterization of the composition of materials based on the interaction of visible–infrared light (electromagnetic energy) with matter. There is potential for use of DRS to increase efficiencies and reduce costs in both large-area applications (e.g., soil survey, watershed management, pedotransfer functions, and soil quality indicators) and site-specific management problems (e.g., precision agriculture, farm advisory services, and process studies). In particular, the ability to rapidly characterize large numbers of samples with DRS opens up new possibilities for risk-based approaches to soil evaluations that explicitly consider uncertainty in predictions and interpretations of soil properties.

BACKGROUND

Near-infrared spectroscopy is routinely used for rapid analysis of a wide range of materials in many laboratory and process control applications in agriculture, food, geology, and biomedicine.^[1] Both the visible–near-infrared (0.35–2.5 μm) and mid-infrared (2.5–25 μm) wavelength regions have been investigated for non-destructive analysis of soils and simultaneous prediction of a number of soil properties.

Although diffuse reflectance spectroscopy (DRS) has been investigated in soils since the 1960s, it is not routinely used in soil analysis. The visible (0.4–0.7 μm) region has been used for color determinations in soil and geological applications as well as in the identification of iron oxides and hydroxides.^[2] There has been only limited success with sensing of soil properties in the field. However, research has demonstrated the ability of DRS to provide non-destructive rapid prediction of soil physical, chemical, and biological properties in the laboratory.^[3,4]

HOW DOES IT WORK?

Physics

Samples are illuminated with an artificial light source, and reflected light diffusing from the sample is collected and channeled through fiber optic cables to arrays of light detectors (Fig. 1). The detectors measure the

amount of light received in narrow wavelength bands (typically 3–10 nm in the visible–near-infrared range) as an electrical signal. The electrical signal in each wave band is expressed relative to the electrical signals obtained from a reference standard. The relative reflectance in each wave band comprises the reflectance spectrum for a sample (Fig. 2), which is displayed and stored on a computer.

The shape of the spectrum is dependent on all the structural groups of atoms that absorb visible and infrared light, which in turn are correlated to the major chemical and physical components of a substance. When light interacts with a sample, light is absorbed to different degrees in each wave band due to electronic transitions of atoms and vibrational stretching and bending of structural groups of atoms that form molecules and crystals. Fundamental features in reflectance spectra occur at energy levels that allow molecules to rise to higher vibrational states. For example, the fundamental features related to various components of soil organic matter (e.g., symmetric C–H stretching) generally occur in the mid-infrared to thermal infrared range (2.5–25 μm), but their overtones (at one-half, one-third, one-fourth, etc., of the wavelength of the fundamental feature) occur in the near-infrared region (0.7–2.5 μm). Soil minerals such as different clay types have very distinct spectral signatures in the near-infrared region because of strong absorption of the overtones of SO_4^{2-} , CO_3^{2-} , and OH^- and combinations of fundamental features of, e.g., H_2O and CO_3^{2-} .^[5] Absorption due to charge transfer and crystal field effects in Fe^{2+} and Fe^{3+} is particularly evident at 0.35–1.0 μm .^[5] However, because soil spectra are a product of many

Fig. 1 Portable visible–near-infrared spectrometer being used to scan a soil sample contained in a petri dish. With this setup, 500 samples per day can be routinely scanned.

overlapping absorption features of organic and mineral materials, they generally have few distinct absorption features. This makes qualitative interpretation of individual features of limited value, but even subtle differences in shape can yield quantitative information on soil properties.

From a theoretical standpoint, mid-infrared spectroscopy (Fourier transform spectroscopy) may be superior to visible–near-infrared spectroscopy because it detects fundamental features as opposed to their overtones and is sensitive to quartz. However, visible–near-infrared instruments are: 1) simpler and more portable; 2) able to scan larger soil samples more rapidly; and 3) better commercially supported than mid-infrared instruments.

Fig. 2 Visible–near-infrared spectra of a range of soil samples from Kenya. The absorption features at 1.4 and 2.2 μm are due to both lattice and free water OH, whereas the adsorption feature at 1.9 μm is due to free water OH only.

Chemometrics

Extracting information about properties of interest from reflectance spectra requires specialized multivariate calibration and classification techniques—the field of chemometrics.^[6] The general aim is to find relationships between measurements made in the laboratory or field that are expensive or labor-intensive and the reflectance spectra, which are easy and cheap to acquire. To obtain robust calibrations, one must minimize information in the spectra that is not relevant to the prediction of the target variable. Various data transformations may be performed to minimize irrelevant information produced by the effects of light scattering, variation due to sample presentation (e.g., thickness, packing, and particle size) and optical setup, and statistical problems such as multicollinearity (correlation among wavelength bands) and non-linearity.^[6] Optimal transformations depend on the individual data set, but first derivative transformation has been commonly used for visible–near-infrared soil spectra.

Multivariate calibration methods are used to relate the measured soil property to reflectance values in a number of different wavelength bands. Methods that include compression of the spectral data are commonly used because of the problem of multicollinearity. The most common methods are principal components regression and partial least squares regression.^[6] However, non-linear parametric regression methods (e.g., multivariate adaptive regression splines), non-parametric regression methods (e.g., regression trees), and classification methods (screening tests using classification trees) have also been used.^[4] Careful procedures for sample selection and validation of calibration models are required to obtain robust calibrations with stable predictive ability.^[6] Standardization of calibration models among different spectrometers can be done by scanning standards on the master and host instruments and simple subtraction of master and host spectra before the unknown sample is predicted.^[7]

Soil Reference Methods

Calibration success will depend on how well the spectroscopic measurement relates to the reference measurement. Ideally, calibration performance should also be assessed relative to the error in reference measurements, e.g., due to variation among duplicates, batches, and laboratories (Fig. 3).

Primary properties of substances that significantly affect the shape of a soil spectrum generally calibrate well to soil reflectance. These include mineral composition, organic matter, water (e.g., hydration, hygroscopic, and free pore water), iron form and amount, carbonates, salinity, and particle size distribution.^[2] Interestingly, these properties also largely determine the capacity of soils to perform production, environmental, and engineering functions. Indirect information about secondary properties of soils (e.g., low

Fig. 3 Soil organic carbon measured in the laboratory against predicted values after calibration to visible-near-infrared reflectance for (A) calibration samples, (B) validation samples (25% of total data withheld), and (C) values for laboratory duplicates. RMSE is root mean square error. Note how the increased error in the calibration and validation data (A, B) at organic carbon values of $>20 \text{ g kg}^{-1}$ is closely related to the error in the laboratory data (C). At organic carbon values of $<20 \text{ g kg}^{-1}$, RMSE was 0.4 for calibration, 1.9 for validation, and 1.3 for laboratory duplicates. Organic carbon was determined by dry combustion on acidified samples for a wide range of Kenyan soils (pH, 4.5–9; clay, 200–800 g kg^{-1} , effective cation exchange capacity per unit mass of clay (ECECclay) = 11–127 $\text{cmol}_c \text{ kg}^{-1}$).

Fig. 4 Degree of correlation (–1 to +1) between soil properties and visible-near-infrared reflectance at different wavelengths, for pH, geometric mean particle size (particle size), effective cation exchange capacity per unit mass of clay (ECECclay), exchangeable calcium (Exch Ca), exchangeable magnesium (Exch Mg), exchangeable potassium (Exch K), modified Olsen extractable phosphorus (Extr P), organic carbon by wet oxidation (Org C wet), organic carbon by dry combustion (Org C dry), total nitrogen (Total N), C/N ratio (C/N ratio), anaerobic incubation mineralizable N (Min N), $\delta^{13}\text{C}$ isotopic ratio ($\delta^{13}\text{C}$), and $\delta^{15}\text{N}$ isotopic ratio ($\delta^{15}\text{N}$). The plots are based on large (>300) samples of diverse Kenyan soils.

concentrations of nutrients in soil extracts, potentially mineralizable carbon (C) and nitrogen, stable isotopes) can also be often obtained because of their interactions with primary soil properties (Fig. 4). For example, DRS has been successfully used to predict cadmium and zinc contamination in floodplain soils because of the associations of these heavy metals with soil organic matter and clay.^[8] Micronutrient concentrations have been predicted from mid-infrared reflectance because of their association with clay mineralogy.^[9] DRS has been used to predict several basic soil properties for a wide range of African topsoils (Table 1).

Merits and Limitations

The main merits of DRS are its repeatability and speed compared with conventional soil analyses. DRS can give better precision and accuracy than the actual reference measurement,^[6] particularly when the error in the reference measurement is large. Thus, repeatability among laboratories is expected to be greater with DRS than with conventional methods of analysis. The speed of analysis and the ability to estimate many soil properties from a single robust measurement are major advantages of DRS, especially for

Table 1 Calibration of soil properties to soil reflectance for a diverse set of African topsoils.

Soil property	No. of soils	Min.	Max.	Calibration data		Validation data

soil properties that are time-consuming to measure by conventional methods. The main limitations of DRS are the need to build calibration libraries for a given population of soils for all the soil properties of interest and the complexity of the data analysis that it involves. Development of global calibration libraries in centralized laboratory facilities and software development for automated data analysis could help to reduce these limitations.

APPLICATION

Soil spectral libraries can be used to generalize results of soil assessments that are conducted at a limited number of sites and thereby increase the efficiency of expensive time-consuming soil-related studies.^[4] The variability of soils in a study area is thoroughly sampled and spectrally characterized. Soil properties or attributes of soil functional capacity are measured on only a selection of soils, designed to sample the variation in the spectral library, and then calibrated to soil reflectance. The soil functional attributes can then be predicted for the entire library and for new samples from the study area. New samples that are classified as spectral outliers to the library are characterized and added to the calibration library, thereby increasing the predictive value of the library.

The spectral library approach has potential for direct and simultaneous prediction of soil attributes for agricultural, environmental, and engineering applications. Because soil reflectance provides an integrated measure of the number of fundamental soil properties, such calibrations could perform better and would certainly be more rapid than pedotransfer functions based on conventional measurements of soil properties.

The rapid nature of the measurement allows soil variability to be more adequately sampled than with conventional approaches and thereby facilitates risk-based

approaches and landscape-level soil assessments, including provision of more sites for calibration to digital terrain and remote sensing information for soil landscape modeling. For example, the authors are applying the approach using spectral libraries composed of thousands of samples to study the effects of historic land use changes on soil quality and to establish baselines for C offset projects. The approach also facilitates soil monitoring because large numbers of samples from repeated samplings can be characterized. For site-specific management, the method allows large numbers of samples to be taken from a field, which may give a better overall estimate of a given soil property than more accurate measurements of the property at a lower sampling density.

CONCLUSION

Developments can be expected toward cheaper and more portable spectrometers, coupled with more flexible software, and easier calibration methods. The technology should be increasingly used in a wide range of soil studies and surveys, and spectrometers are likely to become standard equipment in soil laboratories. Soil spectral libraries will likely form the basis for a new generation of expert systems and probabilistic advisory systems for predicting soil properties and responses to soil management. DRS can also be used for the characterization of organic resource quality for soil management.^[10]

Abstract

The rare earth elements (REEs) comprise the elements scandium ($Z = 21$) and yttrium ($Z = 39$), and 15 lanthanides with successive atomic numbers (Z) from 57 to 71. REEs are applied to soils as fertilizer materials or as contaminations of industrial sludges so that an assessment of their behavior in soils is required for evaluating agro-environmental effects. This entry summarizes the knowledge of soil chemical properties of REEs.

ORIGINS OF SOIL RARE EARTH ELEMENTS (REEs)

Soil REEs mainly originate from parent materials.^[1–6] Application of phosphate fertilizer^[3] and phosphogypsum^[4] can supply REEs to the soil (Table 1). Some of the sludges, particularly those from the chemical industry, have been contaminated with REEs (Table 2). Continuous application of sewage sludges caused an accumulation of scandium and Samarium (Sm) in some soils in Japan.^[6] The use of REEs in agriculture is widely practiced in China. By 2001, 6.5 million hectares of land in China was treated with REE fertilizers.^[2] In total, 11,000 tons of REEs were applied in agricultural production in China.^[7] Besides the parent material, the application of REEs on agricultural farmland is going to be a major source of REEs if the practice of applying them regularly proceeds.

CHEMICAL SPECIATION OF REEs IN SOILS

Total Content

Representative background values of REEs in soils are available so far only for China and Japan.^[1,2,8] The REE content strongly depends on the parent material.^[1] The results of 853 soil analyses showed that the total REE content in soils varied between 18 and 583 mg kg⁻¹, with a mean value of 184 mg kg⁻¹.^[2] The light REEs lanthanum (La), cerium (Ce), praseodymium (Pr), neodymium (Nd), Sm and Europium (Eu) account for 90%

of the total REE content in soils (Table 3). On average, the La, Ce, Nd, Sm, and Eu content was 41, 73, 7.3, 27.5, and 5.6 mg kg⁻¹, respectively, in different soils in China ($n = 467$; Table 3).

Species of REEs in Soils

Binding forms of REEs in soils may be classified according to their availability for plants.^[1] Approximately 9 mg kg⁻¹ is exchangeable, 2, 5, 32, and 95 mg kg⁻¹ are bonded to carbonates, manganese (Mn) oxides, organic substances, and amorphous iron (Fe) oxides, while 59 mg kg⁻¹ is abundant in the form of crystal Fe oxides and 105 mg kg⁻¹ in residual forms (Table 4). Plants utilize exchangeable REEs most easily, while the uptake of other forms is limited.^[1,9] In contrast, residual forms are not plant available.^[1,9]

For determining the content of plant-available REEs, the following extractants have been proposed: 1 M HAc–NaAc (pH 4.8),^[1,9] 1.0 M NH₄NO₃ (pH 7.0),^[10] 0.1 M HCl,^[11] and 0.1 M malic–citric acid,^[12] with 1 M HAc–NaAc being most extensively used.^[1,2] Plant-available REE contents are highly variable and range from <1 to >200 mg kg⁻¹, with a mean value of about 12 mg kg⁻¹ ($n = 1790$).^[1] Physicochemical soil properties such as pH, E_h , cation exchange capacity (CEC), clay, H₂PO₄⁻, and carbonate content have a strong impact on the amount of exchangeable and plant-available REEs.^[1,9] Acid soils contain significantly higher amounts of plant-available REEs than more alkaline, calcareous soils.^[2] The availability of soil applied REEs is usually significantly higher than that in the original soil matrix.^[1,9]

Adsorption of REEs in Soils

In general, 95% of the added REEs are adsorbed.^[13] REEs added to soils are rapidly transformed, e.g., into exchangeable, organic matter–bonded, and Fe/Mn oxide–bonded species.^[1,9] The distribution coefficients for REEs added to red

and yellow brown soils declined in the following order: residual >exchangeable >organic matter–bonded >Fe/Mn oxide–bonded REEs.^[9] The formation of bridged hydroxo complexes is probably the dominant sorption mechanism to clay minerals.^[14] Clay type, pH, CEC, organic matter, and amorphous Fe content regulate the adsorption kinetics of REEs.^[1,2,9] Langmuir and Freundlich equations were found to describe precisely the absorption of REEs in soils.^[1,15]

Translocation of REEs in Soils

The question open is whether the use of REEs in industry and agriculture may result in a pollution of soils, plants, and groundwater. In leaching experiments under controlled

UPTAKE OF REEs BY PLANTS

The uptake of REEs has been investigated for a wide range of plants.^[2,9] All rare elements except Pr were found in plants. Uptake of REEs was related to many factors such as element, plant type, and growth conditions.^[2,9] The light REEs such as Ce, La, and Nd were highest in plants.^[2,9] The total concentration of REEs in plant tissue ranges from <0.05 to 2.58 mg kg⁻¹ (Table 5). The concentration of Ce in food products is usually lower than 0.2 mg CeO₂ kg⁻¹ (Table 6). More attention should be paid to research on the uptake, translocation, and distribution of REEs in plants in order to follow up the biological effects of REEs and to assess agro-environmental effects.

CROP RESPONSE TO REEs

Research with a view to the use of REEs in agriculture was predominantly carried out in China and before in Russia. A small number of studies have been carried out in Australia, too.^[2,9] The increases in crop yield reported by workers from all parts of China range between 5% and 103% (Table 7), with an average response of 8–15%.^[2,9] Crop response to REEs is reported to be most probable when soils contain less than 10 mg kg⁻¹ of available REEs (in 1 M HAc–NaAc, pH 4.8), while a response on soils with more than 20 mg kg⁻¹ of available REEs is unlikely

Table 7 Yield increase (relative to control) after application of REEs to different crops.

Crop	Country	Yield increase (%)
Sugar beet	Bulgaria	17–24
Sugar beet	China	7
Wheat	China	6–17
Rape	China	4–48
Potato	China	5–6
Soybean	China	8–9
Cotton	China	5–12
Rice	China	7
Corn	China	9–103
Barley	Australia	18–19
Peanut	China	8–12
Tobacco	China	8–10
Rubber	China	8–10
Sugarcane	China	10–15
Cabbage	China	10–20
Litschi	China	14–17
Grape	China	8–12

Table 8 Critical values of plant-available REEs in soils.

REE content (mg kg ⁻¹)	Index	Crop response to REE
<5.0	Very low	Most likely
5–10	Low	Probable
11–15	Medium	Not expected
16–20	High	Not expected
>20	Very high	Unlikely

Source: From Liu^[1] and Xiong, Zheng, et al.^[9]

(Table 8). So far, there is no evidence that REEs are essential for plant growth.

CONCLUSION

Basic information about the chemistry of REEs in soils is available, but these data refer to specific regions and soil types. Besides this, the effect of REEs, e.g., on soil fertility and soil biological diversity is yet unclear. Crop response to REE applications depends on various factors, including soil properties. Further studies are also required in order to elaborate the most efficient application techniques.

Redox Phenomena

Bruce R. James

University of Maryland, College Park, Maryland, U.S.A.

Abstract

Oxidation–reduction reactions in soils are governed by the master variables, pH and Eh, and they are controlled kinetically by microbial metabolism and abiotic processes. The heterogeneous, metastable nature of soils makes the study of electron transfers in such environments challenging, but rewarding. Applications of fundamental studies of these processes are readily made to human concerns pertinent to agriculture, environmental quality, and human health.

INTRODUCTION

Electron transfers from electron-rich reductants to electron-poor oxidants in soils change the oxidation state of the electron donor and acceptor, and thereby commonly affect their form, solubility, and mobility. These oxidation and reduction processes involving losses and gains of electrons, respectively, are known as redox reactions, and studying them provides a means to observe and quantify key properties governing the speciation of many elements important in plant nutrition, soil contamination, and soil genesis.^[1–4] Studying how redox conditions change in soils in response to natural and anthropogenic perturbations also provides a way to observe the sensitivity and resilience of soil chemical properties related to electron transfers. Soils are metastable, open systems in a remarkably stable state of non-equilibrium in which electron transfer reactions are controlled by abiotic and biotic processes involving gaseous, aqueous, and colloidal phases.^[5] Interfaces between these phases are centrally important to the energetics and rates of reactions involving redox of soils and natural waters.^[6–8] Many redox reactions in soils involve a phase change for the element transformed, thereby making quantification of the redox status of soils difficult and subject to innovation and new interpretation.^[5] Relatively new understandings of the kinetics of redox reactions in natural waters, particularly as influenced by light, will provide guidance for innovation in the field of redox theory and measurement in soils.^[7,8]

THE NATURE OF THE ELECTRON AND THE PROTON AND THEIR ACTIVITIES IN SOILS

To understand and characterize “electron activity” and oxidation–reduction reactions in heterogeneous, multiphase soils and in soil solutions, an appreciation of the characteristics of electrons and closely allied protons is needed.^[4]

An examination of the complementary nature of electrons and protons affirms the importance of hydrogen (H) ion and electron activities as master variables in soils. The H atom, composed of one proton and one electron, may be visualized and modeled as a spherical puff of cotton candy with a radius of approximately 10 cm and a proton nucleus with a radius of 5 μm —essentially an invisible fleck of unspun sugar in the center! The remaining volume of the atom is occupied by the electron. The density of the spun sugar represents the probability of finding the electron in any one location, and it becomes increasingly thinner (less likely) with distance away from the positively charged proton.^[9] The radius of the H atom (0.3 Å), therefore, is approximately 20,000 times that of the proton (approximately 1.5×10^{-5} Å). The proton also may be visualized as the size of a 0.1 μm colloidal clay particle, compared to a 2000 μm sand grain in soil. In contrast to the large proportion of the volume of the H atom occupied by the negatively charged, wave-like electron, the electron has only negligible mass equal to approximately 550 $\mu\text{g/mol}$, 1/1836 of the mass of the H atom (10^6 $\mu\text{g/mol}$).

In soil chemical calculations and theory, one considers the electron as a “species,” designated “e[−]” with negligible mass and thermodynamically as a ligand, reactant, and product. The electron is not ionic, but it is “negatively charged” as the carrier of negative electricity, as described by J.J. Thompson,^[10] who discovered the electron in 1897. Its “activity” is conceptually analogous to that of H⁺, but its concentration in “mol/L” is undefined. All these caveats about the electron require that one understands that electron activity in soils and natural waters should be regarded as related strictly to energy functions. Such functions can be described simply as “the ability to do work,” “electrochemical potential,” and more colloquially, “electron pressure,” or quantified as a voltage.^[4]

Viewing the sibling concepts of “proton activity” (pH) and “electron activity” (pe) in soils, they must not be considered as twins. Recognition must be given to similarities

and differences in the formulation of conceptual and operational definitions for these key variables, and such comparisons are based on the differences in the nature of the proton and electron, as described above. In both cases, however, thermodynamic activity is defined as the ratio of e^- or H^+ in a given system relative to its activity under standard state conditions. In the case of the e^- , the standard state is at $(H^+)=1$ M, a partial pressure of $H_2 = 1$ atm, and a temperature of 298 K, characteristics of the standard hydrogen electrode (SHE) with 0.00 V under these conditions.^[6,11] For H^+ activity, the reference state is 1 M or pH 0. The measurement of pH and pe as analogous master variables in soils has been classically done with glass and platinum electrodes, respectively. The potential difference between the sensing electrode and a calomel or silver–silver chloride reference electrode is corrected for the potential of the reference electrode relative to the SHE. In this way, an oxidation–reduction potential is converted into a value known as Eh, or the platinum electrode potential relative to the SHE.

The familiar concept of buffer capacity for pH is defined as the change in acid or base added to affect a one unit change in pH.^[6] Similarly, the capacity factor in redox is referred to as poise and is defined as the change in added equivalents of reductant or oxidant to bring about a one unit change in pe (or Eh change of 59.2 mV).^[11] Poise in soils and natural waters has been less intensively studied than pH buffering, but it is a central concept governed by reductant and oxidant activities and by microbial processes. The above discussion of electron and proton activities in soils may be reviewed in more detail in publications.^[4,6]

The U.S. Environmental Protection Agency has developed Mineral Thermal Equilibria (MINTeq), a DOS-based computer program that calculates the distribution of myriad species based on minimizing the Gibbs free energy of a system of multiple chemical equilibria. It incorporates algorithms for redox reactions and allows the estimation of pe, pH, and reductant and oxidant activities in conjunction with dissolution and exchange equilibria. The use of MINTeq also permits an easy way to conduct a sensitivity analysis for estimated pe, pH, or ion activities when just one value for a given parameter is varied.^[12] Other models have been developed and verified for redox-controlled, multispecies systems to predict transport of particular ions.^[13,14]

APPLICATIONS OF REDOX PRINCIPLES IN SOIL ENVIRONMENTS

The thermodynamic and theoretical principles surrounding redox reactions have been used to predict and explain soil chemical phenomena in myriad environments and fields, including paddy rice production, wetland delineation, tidal marsh soil development, rhizosphere function, nutrient cycling, heavy metal remediation, synthetic organic compound cleanup, and other areas pertinent to environmental

protection, agricultural production, and ecosystem function. The coupling of Eh–pH diagrams with empirical measurements of pH, Eh, and activities of oxidants and reductants has proved to be a powerful tool for assessing redox processes in heterogeneous, colloidal environments.

Given the importance of paddy rice (*Oryza sativa* L.) in worldwide production of food, early redox work in soil chemistry focused on the reduction reactions coupled with organic matter oxidation in flooded soils of Asia.^[15] This provided the foundation for more practical applications of microbial and chemical redox reactions to understand wetland function and delineation and to study tidal marsh soil development. These two environments have attracted worldwide concerns over human encroachment into them, with controversies over allowable uses of such “wet soils.”

An environmental concern linking soil redox processes and atmospheric chemistry is that emissions of nitrous oxide (N_2O) from waterlogged soils may contribute to global warming as N_2O absorbs infrared radiation, as do carbon dioxide (CO_2), methane, and water in the troposphere. N_2O is an intermediate product in denitrification, the anaerobic microbial respiration process that converts nitrate (NO_3^-) to dinitrogen gas (N_2) as microbes oxidize reduced carbon compounds to organic acids or CO_2 . The energetics of denitrification and its role in releasing N_2O are summarized in the following equations:^[4]

Reduction of NO_3^- to N_2O by the oxidation of carbohydrate to an organic acid:

Gibbs free energy (kcal per mole of electrons transferred) equals –21 at pH 7.

Reduction of N_2O to N_2 by the oxidation of carbohydrate to an organic acid:

Gibbs free energy (kcal per mole of electrons transferred) equals –36 at pH 7.

Reduction of NO_3^- to N_2 by the oxidation of carbohydrate to an organic acid:

Gibbs free energy (kcal per mole of electrons transferred) equals –24 at pH 7.

The smaller Gibbs free energy of the reaction that produces N_2O from NO_3^- than for the conversion of N_2O to N_2 indicates that the first step in denitrification is less energetically favorable than is the second. This first step requires

higher electron pressures (more reduced soil conditions or lower Eh values) to effect the reduction, and it may be less kinetically favorable also, even though both reactions are enzymatically catalyzed. Soil conditions, such as pH, Eh, temperature, and carbon availability will affect how much N_2O is emitted from soils to the atmosphere rather than being reduced further to harmless N_2 . The overall reduction of NO_3^- to N_2 is energetically favorable, as indicated in Eq. 3, and is intermediate between the first and second steps in terms of energy released. The combination of thermodynamic calculations and kinetic experimentation can provide essential information to predict the nature of the linkage between soil redox processes and global warming.

Redox reactions in the rhizosphere are also important with respect to nutrient availability in this soil environment immediately adjacent to plant root surfaces (within 1 mm or so). On a broader scale, societal concerns about surface and groundwater chemical contamination and eutrophication of surface waters have focused attention on redox reactions with soil profiles as environments where nutrients, especially nitrogen, may undergo oxidation and reduction reactions leading to release of environmentally sensitive forms of nitrogen. For example, nitrification involves the oxidation of ammonium to NO_3^- , a form of nitrogen that is mobile in most soils and is a common pollutant of ground and surface waters.

Soils contaminated with chromium (Cr)(III, VI) or arsenic (As)(III, V) may undergo transformations between the oxidation states of these elements and thereby change the mobility, toxicity, and potential bioavailability of each element. Hexavalent Cr is a soluble and toxic anion, in contrast to Cr(III), a sparingly soluble, non-toxic cation in most soils. Because of this difference in solubility and toxicity of the common oxidation states of Cr in soil environments, reduction of Cr(VI) is being used to remediate soils without changing the total concentration of Cr.^[16] As(III) oxidation to As(V) results in a decrease in the solubility of As, and thereby may prevent contamination of groundwater, as has occurred in years in Bangladesh.^[17]

Synthetic organic chemicals added to soils by humans in wastes or as pesticides may undergo oxidation reactions that usually result in degradation and a decrease in toxicity. Examples are aromatic compounds used as organic solvents in industrial applications and pesticides, such as herbicides and insecticides, that may be retained in soils or be leached to groundwater, depending on redox reactions.^[18]

CONCLUSION

Oxidation–reduction reactions in soils are governed by the master variables, pH and Eh, and they are controlled kinetically by microbial metabolism and abiotic processes. The heterogeneous, metastable nature of soils makes the study of electron transfers in such environments challenging, but rewarding. Applications of fundamental studies of these

processes are readily made to human concerns pertinent to agriculture, environmental quality, and human health.

Rehabilitation: Indicators and Monitoring

David Jasper

Centre for Land Rehabilitation, University of Western Australia, Nedlands, Western Australia, Australia

Abstract

The key role of soil microorganisms in processes of nutrient mineralization and acquisition by plants in sustainable ecosystems means that they are a relevant parameter to measure as an indicator of successful rehabilitation. However, it may be concluded from this integration of measurements from bauxite rehabilitation that plant productivity should be included as perhaps the most important indicator of revegetation success. This is not only because of its primary importance to recovery of soil processes, but also because it integrates all aspects of site fertility. Under the protocols for bauxite mine rehabilitation, it can be argued that if diverse and productive vegetation is successfully established, then appropriate populations of soil microorganisms, and the processes to which they contribute, will subsequently develop.

INTRODUCTION

Measuring soil parameters to use as indicators of ecosystem sustainability or to define soil quality is an increasingly common theme in land management. While substantially more research has occurred in relation to agricultural soils,^[1] the principles developed are equally applicable to soils that are being restored after mining. In the agricultural context, Karlen et al.^[2] listed four functions of soil which were integral to soil quality: 1) accommodating water entry; 2) retaining and supplying water to plants; 3) resisting degradation; and 4) supporting plant growth.

These four functions are equally applicable for rehabilitation of soils disturbed during mining, where reestablishment of a sustainable ecosystem requires vegetative diversity and productivity that are appropriate for the desired end use. Plant productivity, which is a key driver of many processes in a sustainable ecosystem, directly reflects the soil conditions that have been created. Therefore, constructing an appropriate soil environment is the crucial first step in rehabilitation.

The information that needs to be acquired in monitoring rehabilitated soils is a combination of measures that define the starting condition of the soil, together with those that may be more sensitive and can be used to demonstrate change over time (Table 1); e.g., total soil carbon (C) can be considered one of the most important indicators of soil quality and productivity,^[3] yet it is slow to respond to changes in management. As a result, microbial biomass and respiration have been used as a more sensitive indicator of long-term trends in organic matter dynamics in soils.^[4]

In general, indicators of successful ecosystem rehabilitation should have some key characteristics as follows:

1. Accommodate all land uses;
2. Describe generic factors and those that add resilience to the ecosystem;
3. Able to be repeatedly measured to indicate direction of change; and
4. Absolute value needs to be comparable with:
 - a. Premining environment (without specific expectations of replicating it), and
 - b. Postmining/prerehabilitation conditions (with the need to demonstrate appropriate development).

DEVELOPING SOIL BIOLOGICAL INDICATORS FOR ASSESSING REHABILITATION AFTER MINING

Key soil biological indicators may include soil microbial biomass and respiration, incidence of symbiotic microorganisms such as mycorrhizal fungi or rhizobia, and soil invertebrates. Soil microbial biomass is the living microbial fraction (bacteria, fungi, protozoa, microfauna, etc.) comprising 1–4% of soil organic matter.^[4] It is responsible for decomposition and mineralization of organic matter, contributes to soil structure development, and is a source and sink of plant nutrients. The soil microbial biomass has potential as an indicator because it is always present at some level and is very responsive to management changes. The relative proportion of soil microbial C to total soil C has been shown to be a sensitive index of ecosystem recovery in land that was disturbed by coal mining and subsequently reforested.^[5] In general, low or decreasing soil microbial biomass implies low or declining plant productivity.^[4]

Table 1 Selected soil properties that are useful indicators of the capacity of a soil to sustain a restored ecosystem.

Physical fertility	Chemical fertility	Biological fertility
Bulk density	pH	Organic C
Soil strength	Electrical conductivity	Microbial biomass and respiration
Aggregate stability	Plant-available and potentially available nutrients	Soil invertebrates
Water infiltration	Heavy metal availability	
Plant-available water		

Source: Adapted from Karlen, Mausbach, et al.,^[1] Karlen, Wollenhaupt, et al.,^[2] Sparling,^[4] Haigh,^[6] and Doran & Zeiss.^[7]

Mycorrhizal fungi assist in nutrient uptake for most plants and therefore will contribute to the sustainability of revegetation. These fungi can be severely reduced by soil disturbance and stockpiling during mining.^[8] The occurrence of mycorrhizal fungi depends on which plant species are present, and this restricts their potential as a generic indicator of rehabilitation success.

Soil invertebrates are responsible for the breakdown of plant residues, which enables subsequent mineralization, and through their activities, they enhance soil structure. Given their role and their widespread occurrence, soil animals do have potential as generic indicators.^[2,9] In contrast, nitrogen gas (N₂)-fixing microsymbionts have limited potential as indicators because they may have a specific host range and survive well without host plants in topsoils disturbed during mining.

All soil biological components and processes are driven ultimately by C inputs derived from plant production. Zak et al.^[10] demonstrated, on a continental scale, that microbial biomass and organic matter pools were positively related to the annual net productivity of vegetation. This relationship has also been demonstrated at the local scale in bauxite rehabilitation.^[11] In the following case study, Sawada has explored the concept that the rate of recovery of biological processes in rehabilitated mine soils is likely to reflect the productivity of the vegetation that has been established.

CASE STUDY OF THE DEVELOPMENT AND APPLICATION OF INDICATORS

In the bauxite mining industry in southwestern Australia, more than 700 ha of native eucalyptus forests are removed, and a similar area is replanted in previously mined areas every year. It is well recognized that the forest topsoil contains important reserves of viable seed, nutrients, and microorganisms; therefore, this soil is always salvaged

prior to mining.^[12] Where possible, the salvaged topsoil is directly returned to a previously mined area or it is stored in stockpiles until a suitable area becomes available. The relatively uniform nature of the soils and landscapes in the bauxite mining area and the consistent rehabilitation strategies that are applied make it feasible to use chronosequences of rehabilitation to estimate the changes in various soil biological components over time.

In addition to a research in nutrient cycling^[13] and soil development,^[12] there has been considerable research on soil organisms in the rehabilitated bauxite mines of southwestern Australia. These organisms are involved in processes that are essential in nutrient supply and uptake including:

1. mineralization of organic matter (soil invertebrates and soil microbial biomass);
2. enhanced uptake of immobile nutrients (mycorrhizal fungi); and
3. supply of nitrogen through N₂-fixation (rhizobia, *Frankia* spp.).

Total C content in surface soils is substantially lower in topsoils spread again after bauxite mining and increases very slowly, even under highly productive revegetation^[11] (Fig. 1). In contrast, soil microbial biomass increases rapidly and substantially from around 2 to 8 years^[14] (Fig. 1). Its rate and magnitude of response

Fig. 1 The pattern of recovery of total soil C, infectivity of arbuscular mycorrhizal fungi (AMF) (Jasper, unpublished data), soil microbial C (MBC), and the NDVI with increasing age of revegetation following bauxite mining. [Total soil C is expressed as a proportion of the total C in premining forest soil (5.6%), while other parameters are expressed as a proportion of the maximum value reached. Values for total soil C and soil microbial C are derived from the same plots, but the other parameters are each from separate studies using different plots, within the same mining operation.]

Source: From Sawada^[11] and Jasper, Sawada, et al.^[14]

parallel those of the vegetation, and these attributes enhance its utility as an indicator.

Vesicular–arbuscular mycorrhizal fungi follow a similar recovery pattern to that of microbial biomass (Fig. 1). However, they are more difficult to measure and, given their constraints described before, are less suitable as an indicator. Although equivalent time sequences are not available for total biomass of soil animals, Greenslade and Majer^[9] found the total number of “decomposer” species of Collembola and the number of individuals, related very strongly to increasing plant and litter cover. Majer and Nichols^[15] reported similar relationships of ant species richness with plant species diversity and vegetative cover, over an equivalent time course to that in Fig. 1, although ant biomass was not measured.

Plant productivity is not easily measured on a large scale in bauxite rehabilitation. Relevant available data are restricted largely to estimates of cover.^[15] As an alternative, Jasper et al.^[14] used remote sensing technology to estimate photosynthetic leaf area in bauxite rehabilitation, using the normalized difference vegetation index (NDVI) (Fig. 1). The pattern of recovery of NDVI was closely related to that derived from direct measures of plant cover.^[14,15] NDVI values increased rapidly with an increasing age of vegetation in rehabilitated bauxite mines, reaching maximum values after 4–6 years. This rate of increase was more rapid than that of soil microbial biomass or mycorrhizal fungi, which by comparison was delayed by 3–4 years.

CONCLUSION

The key role of soil microorganisms in processes of nutrient mineralization and acquisition by plants in sustainable ecosystems means that they are a relevant parameter to measure as an indicator of successful rehabilitation. However, it may be concluded from this integration of measurements from bauxite rehabilitation that plant productivity should be included as perhaps the most important indicator of revegetation success. This is not only because of its primary importance to recovery of soil processes, but also because it integrates all aspects of site fertility. Under the protocols for bauxite mine rehabilitation, it can be argued that if diverse and productive vegetation is successfully established, then appropriate populations of soil microorganisms, and the processes to which they contribute, will subsequently develop.

The concept of using plant productivity as an integrated measure of rehabilitation performance is mirrored in a research in the Australian mining industry, which is investigating the application of “landscape function analysis” (LFA)^[16] as a tool for assessing mine rehabilitation. In the LFA approach, the capacity of the landscape to retain essential resources of water and nutrients is assessed. This retention capacity reflects both the underlying

characteristics of the constructed landform and the development of plant biomass and soil cover. Thus, it is an integrative measure of plant performance and the factors that affect the performance.

The importance of plant productivity, and its dependence on site fertility, reaffirms the importance of constructing a soil profile with physical and chemical characteristics that are appropriate for the particular vegetation to be established. If the right components of physical and chemical fertility are put in place, together with microbial and plant propagules, the key biological components, then the likelihood of successful rehabilitation is enhanced. In large-scale reestablishment of native ecosystems, such as in rehabilitation after bauxite mining, direct-returned fresh topsoil is the best source of the propagules.

Religious Aspects of Soil—Human Relationships

Abstract

The relationship between soil and humans has been an important part of religious rites and beliefs. The earth, as the basis for human life, is present in cosmogonies as mother earth and as an “element,” a basic constituent of natural bodies and humans alike. Ancient Greek and Roman, Chinese, Buddhist, Hindu, Inca, and the Abrahamic religious systems emphasize the spiritual aspects of human interventions (such as plowing) into soils. Worshipping the soil and a ritual framing of the central agricultural operation, plowing, are common in primal religions. While the Chinese are the only ones who developed a soil altar, the earth as the basis for all life is acknowledged in almost all primal belief systems. Studying the religious aspects of human relations to soils does allow us to appreciate the multifaceted ways of how societies dealt with the ambiguity of being human, being at once a part of and apart from nature.

INTRODUCTION

Since the advent of agriculture, dealing with the soil was the central pursuit of humans. Agriculture was as much a way of living as the mainstay of economy in the agricultural civilizations. The relationship between soil and humans was central to both individual subsistence and social life and was also an important part of religious rites and beliefs.^[1]

There are many, scholarly disputed definitions of “religion.” All religions contain three basic elements: systems of belief, ways of life, and important shapers of identity.^[2] According to Gottlieb, religions are “organized and overlapping systems of belief, ritual, institutional life, spiritual aspiration, and ethical orientation which are premised on an understanding of human beings as other or more than simply their purely social or physical identities. Religions also provide guidance that seeks to root everyday moral teachings in the ultimate nature or significance of a spiritual truth about who we really are. Religions therefore direct us toward particular ways of living with other people and with the world. Finally, religions provide rituals—acts of prayer, meditation, collective contrition, or celebration—whose goal is to awaken and reinforce an immediate and personal sense of our connection to the Sacred.”^[3]

When dealing with religious aspects of human relations to soils, two major kinds of religions need to be distinguished. Natural religions are those which embrace

all members of the society in question; taking part is an obligation. All small societies have such a religion; its main features are a myth of origin, care for the ancestors, rites of transition, and calendar rituals. This kind of religion is called “primal religion.” The expression “primal” means that historically it has a certain priority and that the basic aspects of religion are found within it. “Salvation religion,” “critical religion,” or “guidance religion” come under the second major type of religion. These religions are founded by religious leaders who offer a distinctive message against the usual assumptions of the society in which they live. Most major religions of the world belong to this type. During the complex history of humankind, Buddhism, Christianity, and Islam established themselves as major religions. As a result, they adapted themselves to various social and political pressures and adopted some of the functions of primal religions.

Over the long run of human history, when primal religions were dominant, soils were conceptualized as part of a world that was controlled by higher, unseen powers. Thus, soils were considered to bear immaterial qualities; they were—to some extent—objects of religious reverence and corresponding ritual practices to ensure their sustained fertility existed. Before giving an overview of religious concepts worldwide, a word of caution is needed. Comparative approaches to religions are fraught with difficulty. Translations are particularly problematic with transcendental concepts.

To discuss religions completely, we would need to consider their conceptual, behavioral, social, and subjective aspects. This entry focuses on conceptual aspects, discussing the earth's role in cosmogonies and the ritual aspects of dealing with the soil.

EARTH AS PART OF BELIEF SYSTEMS

The earth, as all-encompassing basis for human life, is presented in cosmogonies in two different forms: 1) as mother earth, deified as a numinous deity, with her body and organs as the different parts of nature and 2) as an "element," which is considered as a basic constituent of natural bodies and humans alike. The cult of the "mother earth goddess" is not directly a cult of the soil, and creation myths do not refer to the soil. Tillers of the soil come late in many cosmogonies, as a second inhabitant living on the earth.

Nevertheless, the earth plays a central role in most religions. For example, the Greek philosophy of nature knew four elements: earth, water, air, and fire. Its Chinese counterpart has five constituents: metal, wood, and again, earth, water, and fire. The Buddhist mahabhuds are water, soil, fire, air, and space. The Sanskrit word "*dharat*" is like "*bhumi*" a word for "soil," which is, at least in the Atharvaveda (XII.I), the deified subject of a hymn praising it as ruler and mother. The hymn mentions different types of soil. Another word for earth, "*prithvi*" and "*vasundhra*" are the most common names of the Hindu earth goddess and also one name of the element of earth in the fivefold cosmogony of Hinduism, comprising of earth, water, fire, air/wind, and ether.

In Greek cosmogony, the first beings are the giants. Gaia (Gea), the earth as goddess, according to Greek mythology the only being that emerged from primeval Chaos, Poseidon, and the Greek god of the sea, are the parents of the Giant Antaios. Antaios challenged all travelers passing his realm to a wrestling match, which he always won. He was slain by Herakles because the hero lifted the giant off the ground. Whenever he had fallen to the ground in battle before, touching the earth had regenerated his powers. The earth as embodied in the giant's mother Gaia plays a powerful role in this myth.

The concept of earth's healing powers has been preserved in European folklore over the millennia. In German folk belief, newborn babies were ritually placed on the earth to gain strength, as well as sick people, for the same reason. Magicians and sorcerers, much like Antaios, were believed to be able to escape when they touched the earth, and after capturing them, they had to be suspended above the ground. Swallowing a piece of earth was believed to heal hiccups, and after a snake bite, the affected limb was to be put into fresh earth.

Earth deities can be found in many religions. A Germanic Goddess called Nerthus was considered similar to

Tellus, or Terra mater, the Roman Gaia-analogue, by the Roman author Tacitus. These goddesses are most often chthonian (belonging to the underworld), and not fully, if at all, personalized. They are seen as primeval in many mythologies and embody the universal truth that all life comes from earth and reverts to earth after its death.

Place-based deities, owners of the space of a people, are also common in many religions. They are responsible for fertility, but their connection to soil is indirect. They are associated with the fruit of the land rather than with the soil as such. The Roman *Penates* and *Lares* can be subsumed under the category of place-based deities. They are both part of ancestor worship and a place-based (House of God) idea of bringing fertility and luck. There are shrines to ancestors and the spirits of a given home in many belief systems, but their relation to soil is an indirect one.

THE SPIRITUAL ASPECT OF HUMAN INTERVENTIONS INTO SOILS

One of the oldest European works with reference to agricultural practices, Hesiod's "Works and Days," is an example for the role of soils, or even more precise, of tilling the soil, in a primal religion's worldview, after the change from the chthonian deities Gaia and Chronos to the Olympic pantheon. Hesiod's poetic program is based on an immanent god. The divine will is not discovered by reading sacred or philosophical texts but rather in the day-to-day world in which he lives. Zeus' will is manifested in the life of the people. What succeeds in the world is what Zeus has prescribed for humans. Farming, which is the necessary way in which humanity procures food, is, therefore, necessarily also the will of Zeus. Farming knowledge in such a belief system is knowledge necessary to perform the will of the divine beings and has, therefore, a sacred dimension. Hesiod does not describe soil altars or rituals to it. Human life conduct is the main vehicle of worship. Tilling the soil well is a prerequisite for spiritual fulfillment. The various deities governing the conduct of agriculture in Greek and Roman mythology are part of the system Hesiod describes, a system in which the conduct of agriculture as the main worship to the Gods was also perceived as being at their mercy. The Greek/Roman Ceres/Demeter is one example for a powerful divine representation. The pantheon around agricultural operations was much differentiated in ancient Rome. Agricultural deities, while connected to the soil, are different from earth goddesses as they do not symbolize the entire universe or the earth, and they are also different in that they are most closely connected to the harvest and not to the fertility of the soil as such.

Many primal religions harbor similar concepts, in some cases, especially with Nomadic people, they can be of

opposite character: Touching the soil with an implement can be forbidden, and a spiritually fulfilling life requires not to touch the soil for planting.

As in other agrarian civilizations, a system of “elements,” of primary matter, was developed in Hellenic philosophy. Anaxagoras (ca. 500 B.C.E.) is said to have been the first to develop the scheme of the four qualities, namely hot, cold, wet, and dry, from which the qualities of the four elements are derived which lie at the very heart of Greek nature concepts. In Fragment 4, these four opposites were specifically mentioned, along with the bright and the dark, “much earth” and “innumerable seeds” as part of the primeval mixture, when all things were together. Earth does have a special place in this cosmogony. Empedocles, 4th century B.C.E., gives the earth none of the four qualities but rather identifies it with solidity, not unlike the earlier Anaximenes, who relates hot and cold to differences in density (rare/dense). Both Anaximenes and Empedocles describe qualities of the earth that are relevant to agriculture (density and solidity), rather than trying to abstract from it completely. Only their later readers and commentators rendered earth as one of the four abstract elements, which are the basis of later philosophy. This allows us a glimpse of how an abstract worldview such as Greek natural philosophy was developed on the basis of an earlier, perhaps more practical relation with the earth.

In ancient China, during the Sui and T’ang dynasties, starting from the late 6th century, a ritual honoring the earth was performed by the emperor on the day of the summer solstice. Other rituals were performed to honor the holy soil of China (Shên Tsou) or the Great Earth Deity (Ta-sheh).^[4] Later on, local soil altars were integrated into the greater belief system of Daoism. The best known part of this worship, and a major tourist attraction in Beijing, is the Altar of the Earth and Heavens in Sun-Yat-Sen Park, dating back to the 14th century. In it, hard-packed earth in five colors, yellow in the middle, green to the east, white to the west, red to the south, and black to the north is at the center of worship.

Plowing is the most significant agricultural operation, the one that engages most deeply with the soil. We know of ritual plowings in many religions and cultures. For ancient Greece, three locations of ritual plowing are known, one in Skiron, second one close to Eleusis, and the third one under the Akropolis in Athens. These have to be considered as a part of rites for Demeter, the goddess of fertility.^[5] During the Sukhothai Kingdom (13–15th century C.E.) in Thailand, a royal plowing ceremony was first recorded. After a lapse of 40 years, the Thai kings reinstituted it in 1960, and it is held every year in May. It is similar to many other plowing rites: A pair of sacred oxen is hitched to a wooden plow, opening a furrow on ceremonial ground.

The corresponding Inca rites are described in a report by a Spanish-Inca writer, Garcilaso de la Vega. According to him, a terrace in Cusco was tilled exclusively by those of royal blood (the Inca). Of special celebrations, songs

were based on the word *hailli*, which means triumph over the soil, which they ploughed and disemboweled so that it should give fruit (Garcilaso de la Vega 1989 (1609): 244, quoted after Bauer).^[6] It is important to point out that in the Inca tradition, agriculture and warfare were closely related ritually, and the furrowing was described in martial terms.

While primal religions almost universally ritualize the act of plowing or more generally, tilling, the Abrahamic religions, although they make frequent allusions to soils, do so only metaphorically. The Bible does not invoke any worship of the soil, as it—like all other Abrahamic religions—is directed against a numinous world view. This is not to say that there is no ecological awareness in these works. Much is yet to be learned about the European and also about the Jewish tradition. Of particular interest as an ecological concept is the Sabbat, the 7th day on which nothing in nature must be changed, a day of rest for nature, and the 7th year, in which fields shall rest. The etymological connection between the Hebrew words adam (man, in particular Adam, the first human in the Old Testament) and adamah (soil) has been discussed widely and controversially. Jewish Environmentalists drew on the connection to argue for a Jewish eco-theology, and a wealth of books on such issues has been published in the last years. The Judeo-Christian tradition is abundant with references to soils. The Bible contains multiple references to soil and its fertility, such as the Old Testament’s Psalm 65, 10, or Job 31, 38–40, in which the barrenness of the earth is invoked at the very end of Job’s plea, as the last and ultimate imaginable catastrophe. The interaction of the soil with seed is used as a metaphor to describe human souls and their ability to receive the word of the Lord. As an example from the New Testament, Mark 4, 3–9 shall be noted, where different soils are described on which the seed falls, with different results.

CONCLUSION

Worshipping the soil and a ritual framing of the central agricultural operation, plowing, are common in primal religions, and while the Chinese are the only ones who developed a soil altar, the earth as the basis for all life is acknowledged in almost all primal belief systems. In the cases of earth goddesses, the principle of fecundity was the focus of worship. They stood for all nature, for the rejuvenation of plant and animal life in the cycle of the seasons. Earth goddesses were no soil goddesses but embodied nature goddesses. Place-based deities are no soil gods either; again, soil fertility was conceptualized as part of the qualities of a particular place. The worship of the soil did not keep people from destroying it, unintentionally, through their efforts to procure a living from the soil, and there is no direct connection between the belief system and human actions. Studying the religious

aspects of human relations to soils does allow us, however, to appreciate the multifaceted ways how societies dealt with the ambiguity of being human, being at once a part of and apart from nature, a question that has not seized to be of importance.

ACKNOWLEDGMENT

This entry is based mainly on a longer discussion of the subject by the authors.^[1]

Rendzina

Thomas E. Fenton

Soil Morphology and Genesis, Agronomy Department, Iowa State University, Ames, Iowa, U.S.A.

Abstract

The term Rendzina has a long history of use to describe shallow soils that are calcareous and are underlain by parent materials high in carbonates. Based on the classification systems, it appears that the term Rendzina will be used less frequently in the future. However, the use of the “rend” root of the word will continue at least in Soil Taxonomy and the Food and Agriculture Organization–United Nations Educational, Scientific and Cultural Organization soil classification systems.

INTRODUCTION

Rendzina is a term that has a long history of use on a worldwide basis. In soil classification, it has always included soils high in carbonates. Most countries, except the United States, have used the name to describe shallow to very shallow soils, gray to black in color that developed in limestone or chalk. Early usage in the United States differed in that. Rendzinas included deeper, dark soils with profiles ranging from 38 to 152 cm in thickness, with many, but not all containing carbonates.^[1]

The origin of the word “Rendzina” has a complex history. Simonson^[2] described the original use of Rendzina as a folk term used to convey the clinking sound of a plow being drawn through certain stony soils. In the late 19th century, Polish scientists began using the name for soils formed in highly calcareous materials. Part of Poland was then in the Russian Empire, and the name was used in some of the early Russian soil classifications.

HISTORY OF USE

De'Sigmond^[3] described the conditions needed for the development of Rendzinas as parent rock rich in calcium carbonate or gypsum that has the fineness of structure and solubility necessary to neutralize the podzolizing effect of the humid climate under which they developed the forest vegetation. He considered these soils to be azonal, i.e., they did not have completely developed profiles.

Robinson^[4] described the Rendzinas of Central Europe as humus-carbonate soils. They were typically dark colored soils with 3–12% organic matter and varying amounts of free calcium carbonate. In the Russian classification system proposed by Glinka,^[5] Rendzinas were considered to be typical endodynamomorphic soils, which had not yet reached mature development, and in which the profile character was mainly determined by the nature

of the parent material. Glinka^[5] observed that these humus-carbonate soils usually contained considerable undecomposed rock, the amount of which decreased in soil development. All the Rendzina soils described by Glinka^[5] are shallow soils similar to those described by De'Sigmond.^[3] As described by Glinka,^[5] the A horizon was 15–30 cm in thickness with varying amounts of limestone fragments and graded through a thin transition of lighter-colored material into fragmental limestone at about 46 cm or less. Spanish red soils regarded as terra rossa were thought to be formed by the degradation of Rendzinas, consequent on deforestation under semiarid conditions. The placement of Rendzinas as endodynamomorphic soils was later criticized by Marbut^[6] because he thought Glinka's^[5] groupings were poorly balanced, in that they represented such a small part of the total soils of the world as compared to the more fully developed soils. Rode^[7] used the term “turfy-carbonate” soils as a synonym for Rendzina for Russian soils within Podzol zones. The presence of the high carbonate content in the parent rock resulted in a high content of calcium carbonate humus and was thought to have prevented these soils from becoming podzolized.

Marbut^[8] in his final classification system included Rendzinas in Category III which he defined as those soils in which extreme youth, excessive erosion, wetness, and excessive contents of carbonates, salt, or alkali prevented the development of normal soil. Rendzinas were the soils with excessive contents of carbonates.

Baldwin et al. retained the Rendzinas as intrazonal soils in their highest category order, calomorph in the suborder level, and named Rendzina as a great soil group. A general description of the soils included as Rendzinas in this classification system was an intrazonal group of soils, usually with brown or black friable surface horizons, underlain by light-gray or pale-yellow soft calcareous material, developed under grass vegetation or mixed grass and forest vegetation, in humid and semiarid regions from relatively soft, highly calcareous parent material.^[9]

After 12 years of the publication of the abovementioned soil classification system, Oakes and Thorp^[1] suggested that some of the soils included as Rendzinas, such as Houston Black, were markedly different from the Rendzinas of Europe. The included soils they objected to, were high in clay, generally dark in color, free of stones, and were deep soils. Many but not all were calcareous. The common property was shrink–swell that resulted in churning of the soil. They proposed that these soils be reclassified within a great soil group named Grumusols and developed a tentative definition. This proposal gradually gained acceptance both in the United States and other countries. The acceptance of the grumusol concept substantially reduced Rendzina soils to a minor group in the United States. Oakes and Thorp^[1] observed that the Lithosols of the prairies of the Southern United States conformed more closely to the Rendzina of other countries rather than the medium depth and deep soils that had been included with rendzinas in the United States.

Papadakis^[10] characterized the Rendzina group as those soils that contained active carbonates and gave effervescence with hydrogen chloride in all their horizons. He attributed the deep, dark accumulation of humus to the carbonate environment. As climate became drier, the accumulations of humus were less and desert Rendzinas (serozems) lack humus.

Bridges^[11] discussed Rendzinas in the category of intrazonal, calcimorphic soils. He described rendzinas in the following way: a shallow soil rich in organic matter and biological activity. It has a stable crumb structure and is dark in color. It is a relatively simple soil with an A horizon directly overlying a C horizon, which is the limestone parent material. The humus is well incorporated in the mull form and micromorphological evidence showed that these soils are largely composed of the fecal pellets of soil arthropods and the casts of earthworms.

PRESENT USE

A part of the word Rendzina is used in the U.S. soil classification system—Soil Taxonomy.^[12] The “rend” part of the word was used to coin a new term for a suborder in the Mollisol Order—Rendolls. The term was used to convey the concept of a high level of carbonates in these soils. Many of the soils previously called Rendzinas are included within the Mollisol Order and the Rendoll Suborder in Soil Taxonomy. Rendolls have mollic epipedons less than 50 cm in thickness that are underlain by calcareous parent material or a cambic horizon with a high carbonate content. The parent material is limestone, chalk, drift composed mainly of limestone, or shell bars. They occur in humid climates (udic moisture regimes) or cold climates with temperatures lower than 8°C (cryic soil temperature regime) or both and have a high calcium carbonate content (calcium equivalent of 40% or more) in the mollic epipedon or in the underlying mineral material. The native vegetation is thought to be forest or grass and shrubs. They are

not extensive in the United States but on a worldwide basis occupy approximately 0.2% of the land area.

Rendzinas were recognized in the Food and Agriculture Organization–United Nations Educational, Scientific and Cultural Organization (FAO–UNESCO) system for soil shallow to limestone prior to 1988.^[13] However, this term was dropped in the 1988 revision.^[14] These soils were then included with the Leptosols or thin shallow soils. The term rendzic is an adjective in the FAO–UNESCO legend having been added in 1988 and is used for naming map units at the second level.

CONCLUSION

The term Rendzina has a long history of use to describe shallow soils that are calcareous and are underlain by parent materials high in carbonates. Based on the classification systems, it appears that the term Rendzina will be used less frequently in the future. However, the use of the “Rend” root of the word will continue at least in Soil Taxonomy and the FAO–UNESCO soil classification systems.

Resilience

Moses M. Tenywa

J.G.M. Majaliwa

Department of Soil Science, University of Makerere, Kampala, Uganda

A. Lufafa

Makerere University, Kampala, Uganda

Abstract

The soil resilience concept is relatively new and has emerged alongside the efforts to define and measure sustainability of agricultural systems. Various efforts to define soil resilience can broadly be grouped into three categories: as a process, nature, and soil state. Soil resilience as a process focuses on the mechanical role of soil in countering degradative processes. The nature concept is defined as the ability of the soil system to remain productive through efficient processing over an extended period of time. The state concept views soil resilience as a lumped, dynamic macroscopic parameter that is a consequence of fine-scale interactions between properties, processes, microclimate, and management impacts within the soil body.

INTRODUCTION

The soil resilience concept is relatively new^[1,2] and has emerged alongside the efforts to define and measure sustainability of agricultural systems.^[3] It describes the level of resistance to forces driving soil degradation, and provides insight into mechanisms that endow soils with favorable properties and beneficial processes from physical, chemical, and biological perspectives. Like sustainability, which has remained a difficult concept to elucidate, the soil resilience concept is inexactly expressed^[4,5] and quantified, yet it is recognized as the most relevant parameter for understanding and management of soil ecosystems.^[6] Various efforts to define soil resilience can broadly be grouped into three categories: as a process, nature, and soil state.

A PROCESS

Soil resilience as a process focuses on the mechanical role of soil in countering degradative processes (e.g., rainsplash and detachment). It refers to the ability of the soil to resist or recover when subjected to degradative forces. This definition is primarily inspired by the Hooke's spring elasticity model. Using this model, a soil resilience coefficient was proposed as follows:^[3]

$$S_r = -2A/x^2 \quad (1)$$

where S_r is the resilience coefficient whose inverse indicates vulnerability to degradation; A is the amount of work required to move soil from one state to another (e.g., 1–2), and x is the variable reflecting changes in soil state.

A resilient soil, therefore, exhibits a higher S_r and minimal change in soil state (x) as stress accumulates. Although the analogy is satisfactory when used to elaborate resilience of the physical soil system, its utility is limited on five major premises:

1. Lack of means to translate the chemical, biological, and other forms of work into “unified mechanical form.”
2. The absence of a lumped parameter adequate in capturing “wholly” the changes in soil state.
3. Assumes classical resilience to be characteristically independent of stability. Yet for soil systems, the two may not necessarily be mutually exclusive, in that alterations in resilience from equilibrium may result in deterioration of soil structural attributes.
4. Eq. 1 holds if the alterations are slight and temporary. Otherwise, if the soil system undergoes irreversible changes and the degree or duration of perturbations is drastic and intense, the relationship ceases to be valid.^[7]
5. The model describes the macroscopic behavior of the soil matrix and therefore does not give a complete picture of what is happening at finer levels of soil organization.

A NATURE

This school of thought focuses on the functional integrity of the soil judged, based on its properties (e.g., soil formation stage, degree, and level of use/management), and

is the most common approach found in the work done by Lal.^[7] Soil resilience from this perspective is defined as the ability of the soil system to remain productive through efficient processing over an extended period of time.^[4,8] Accordingly, it refers to the longevity of the soil resource and its health measured in terms of overall performance and quality.^[9] The mass flux balance approach^[4] is typically used to express the functional integrity of the soil in the form of a soil resilience factor:

$$S_r = S_a + (S_n - S_d + I_m)dt \quad (2)$$

where S_r is soil resilience, S_a is the antecedent soil condition, S_n is the rate of new soil formation, S_d is the rate of soil degradation/depletion, and I_m connotes the management inputs from outside the ecosystem.

The major limitation of this approach lies in its failure to account for the impact of restorative processes (buffering capacities of soil) on the prevailing soil properties, that is, focuses on the “what” of the antecedent state has changed as a result of the interaction of soil formation, degradation, and management, but overlooks the mechanisms of change—the “how.”

A STATE

The state concept views soil resilience as a lumped, dynamic macroscopic parameter that is a consequence of fine-scale interactions between properties, processes, microclimate, and management impacts within the soil body.^[10] Difficulties exist in the development of a single indicator of soil resilience because the soil consists of at least three “states,” its physical, chemical, and biological properties (each of which consists of numerous subproperties), which interact in a complex manner but are quantified through extremely different procedures. Seen as a combined effect of both soil-buffering capacities (physical, chemical, and biological) and soil mass flux balance because of pedological and anthropological actions, a resilience factor as described by the following equation was suggested:^[3]

$$S_r = BC_{ph} + BC_{ch} + BC_b + (r_p + r_a)dt \quad (3)$$

where S_r is soil resilience, BC_{ph} is physical buffering, BC_{ch} is chemical buffering, BC_b is biological buffering, r_p is rate of pedological soil fluxes, r_a is rate of anthropological fluxes, and dt is change over time.

Although this approach is process based, its major limitations emanate from the assumption that the named different soil “states” are independent, ignoring their known interactions.^[8] Nonetheless, this “state” approach to resilience combines the three fundamentally different components of the soil, and as such is worthy of attention by those who seek to quantify soil impacts in a holistic manner.

With respect to agronomy, soil productivity is a crucial indicator of soil resilience. Although soil productivity also remains difficult to quantify,^[11,4] crop yield over time is a practical measure of productivity.^[11,12,13] Long-term crop performance under specific environmental and management conditions is mainly dependent upon relevant soil depth (RSD) characteristics.^[14,15] Assuming an infinitesimal pedon, a productivity index D_p of specific productivity level P ranging from P_{min} to P_{max} yield can be defined in a manner similar to the degree of polarization^[16,17] by the use of statistical mechanics on an RSD matrix, as:

$$D_p = 2(P - P_c)/g \quad (4)$$

where $g = (P_{max} - P_{min})$ is the maximum agroecological productivity gap, and $(P - P_c)$ is the gap between specific productivity level P and the critical productivity level $P_c = (P_{max} + P_{min})/2$ of the agroecological zone. D_p ranges from -1 for highly degraded (HD) land to $+1$ for highly productive (HP) land, insinuating the existence of three resilience phases: namely, high resilience (associated with HP), marginal resilience (associated with HD), and diminishing resilience (transitional phase).^[5]

The major advantage of using D_p as an index of soil resilience is that it is a macroscopic state parameter derived from microscopic properties. Considering that the soil can exhibit more than one accessible state (configuration of pedon of specific parameters of state; e.g., temperature, energy, chemical potential, volume, and pressure) at different equilibria, D_p provides an excellent opportunity for capturing all of them.^[5]

Finally, it is noteworthy that a similar index ($D_p = P/P_{max}$) for crop productivity is used in land evaluation and suitability assessment,^[18] and Eq. 1 can be applied near the limit of the HP macrostate. However, a great challenge remains to establish a state parameter for non-agricultural soils.

FACTORS AFFECTING SOIL RESILIENCE

The factors that affect soil resilience fall in two broad groups, namely, endogenous and exogenous.^[4] Endogenous factors are related to the inherent soil properties (e.g., soil depth, relief, drainage status, structure, texture, soil organic matter, humus quality, faunal and floral activities, and nutrient level) and climate especially precipitation.^[19] Exogenous factors are largely a result of land use and management. Good management aims at providing a buffer against sudden fluctuations in the system, minimizing degradative effects of atmospheric agents (e.g., heat, wind, rain, and runoff), enhancing restorative mechanisms, and providing adequate protection to soil against degradation. Several methods of management exist that impact resilience factors: agricultural operations

(e.g., irrigation, tillage, drainage, terracing, ridging, mulching, crop, and water harvesting) influence weathering, soil formation, and synthesis and hence the direction of the degradative process.

The net balance of interaction between the two categories of factors (exogenous and endogenous) determines the predominant mechanism, rate, duration, and direction of beneficial processes in soil.^[20] Under unsuitable land use and/or poor management, the restoration capacity of the beneficial processes becomes undermined and the net force balance is tilted negatively toward soil resilience by endogenous factors, hence the prevalence of the degradation mechanisms include:

1. Progressive removal of the top soil layer by soil erosion, tillage erosion, soil mining (e.g., brick making and sand quarrying).
2. Destruction of soil structure/matrix by bad tillage.
3. Nutrient depletion through crop uptake, harvest, and burning.
4. Degradation of subsoil by leaching of aluminum (Al) and silicon and formation of allophane and imogolite from residual silica and alumina.^[21]

On the other hand, when land is well managed, the positive effects of exogenous factors on soil resilience accrue through the following restorative mechanisms:

1. Invasion of subsoil by micro-organisms.
2. Subsequent differentiation of subsoil and plant succession (decomposition and humification).
3. Weathering enhanced by soil and water conservation measures of stabilization.^[21]
4. Silica absorbed by plants to form plant and Al-humus complex, which makes up the thick A horizon peculiar to the black soil.^[22]

CONCLUSION

Notwithstanding the great progress of years in the development of soil resilience theory, there is a pressing need for development of a more adequate, single measure of soil resilience that can be used by soil conservation/land husbandry engineers who are commonly confronted with various combinations of land degradation forms.

Resilience: Land Use and Soil Management

Soojin J. Park

Department of Geography, Seoul National University, Seoul, Korea

Abstract

Soil resilience is a relatively new concept in soil science and land management studies, and the understanding of soil resilience and interaction with soil and land management are rather qualitative and descriptive. Soil degradation trends give an alarming signal to the security of food production. Historically, the rapid increase of agricultural production has been achieved by the intensification of land use and the use of agrochemicals, but conservative soil management practices attract more attention than high-input agriculture in order to reduce soil degradation and agriculture-related pollution. The basic principles for conservative soil management are how to reduce the destructive influence of soil management practices within the resilience potentials of soils and what is the most appropriate soil management to maintain or even improve soil resilience characteristics in given natural and socioeconomic conditions. Our improved understanding of the processes in soil, water, and plant ecosystems in relation to highly variable local environmental conditions is essential for these tasks.

INTRODUCTION

Most human activities associated with land use cause direct and indirect changes in soil-forming processes and soil properties. Urban and industrial development might be the most destructive form of soil disturbance, causing total removal of existing soil layers, introduction of hazardous chemicals into soils, or drastic changes in soil-forming processes within a short time period. Even though the rate of change is slow and adverse effects are not clear in the short run, agricultural activities are also greatly contributing to soil disturbance and consequent loss of soil resilience. Land use practices and their influence on soil resilience are so diverse that it is virtually impossible to describe them in detail. Discussions here are mostly limited to agricultural land use in which soil management practices are essential human interventions to maintain agricultural production. A more theoretical discussion on the influence of other land use systems on soils may be found elsewhere.^[1,2] For agricultural land use, one should also note that the influence of certain soil management practices on soil resilience varies widely depending on soil types formed as a result of highly interacting environmental factors. The ignorance of the intrinsic and spatial variability of soils and environmental conditions may result in significant reduction in crop production and accelerated degradation of soil resources.

BASIC CONCEPT

Soils are the product of the highly complex interactions of many interdependent variables that have been categorized

as the five soil-forming factors: climate, parent material, organisms, topography, and time. Under natural conditions, soil evolves along two developmental pathways: progressive and regressive.^[3] The progressive pathway of soil evolution includes conditions, processes, and factors that promote horizonation, developmental upbuilding, and/or soil deepening. The regressive pathway promotes haploidization (destruction of soil horizons), retardant upbuilding, and/or subsurface removal. Either of these two pathways may be dominant for a soil in a given location, resulting in a steady state or equilibrium of a soil's physical, chemical, and biological properties in a given environment. Any kind of soil management practices leads to changes of such a steady state and accelerates either progressive or regressive pathway.

It does not necessarily mean that soils in progressive pathways are more beneficial for agricultural and engineering use than soils in regressive pathways, but soils in progressive pathways are more likely restored after temporal disturbances induced by soil management by favorable soil-forming conditions. Continuous or sometimes catastrophic dominance of regressive pathways caused by both natural processes and poor soil management may lead to the loss of resilience and even irreversible degradation of soils. However, it might also be possible to reverse the regressive pathway of soils and to restore highly degraded soils with good management and appropriate technological input. The main question in maintaining soil resilience for sustainable agriculture or other human activities is how to minimize the regressive influence of human-induced soil disturbance within the range of progressive pathways of soil formation, which can be modeled:

$$S_r = S_a + \int (S_n - S_d \pm I_m) dt$$

where S_r is the soil's resilience, S_a is the antecedent soil condition, S_n is the rate of new soil formation (progressive condition), S_d is the rate of soil degradation/depletion (regressive condition), and I_m is the management inputs from outside the ecosystem.^[4]

AGRICULTURAL SOIL MANAGEMENT EFFECTS ON SOIL RESILIENCE

Most land use practices have largely been accelerating regressive pathways of soil formation, which is evidenced by rapid soil degradation worldwide.^[5] Agricultural land use is one of the main land uses contributing to such soil degradation processes along with deforestation and overgrazing. Table 1 illustrates progressive and regressive changes induced by soil cultivation. When the original vegetation is removed for cultivation, the soil surface exposed to air

becomes vulnerable to air and wind erosion. It also modifies the microclimate of the near-ground atmosphere. With continuous cultivation, organic matter levels in soil gradually decrease. The decrease of organic matter causes the deterioration of soil structure, reduction of microbial activities and cation exchange capacity, increase of nutrient leaching, and sensitivity to erosion. The use of heavy machinery for tillage and farm traffics destroys soil structures and increases soil compaction, which greatly accelerates erosion processes.

Agricultural soil management can be grouped into five major activities: 1) tillage; 2) maintaining organic material content and nutrients; 3) application of agricultural chemicals; 4) drainage and irrigation; and 5) mechanical control of erosion. In addition to the mechanical control of erosion, soil erosion control is the most important consideration in selecting the different tillage types and maintaining the organic matter content. Tillage is frequently divided into two groups: conventional and conservation tillage. Conventional tillage turns over surface soils using a plow in order to remove weeds and to provide sufficient moisture and nutrient for planted seeds. Conservation tillage includes various tillage

Table 1 Possible progressive and regressive alteration of soil-forming factors by agricultural land use and soil management.

Soil-forming factor	Progressive influence	Regressive influence
Parent material	Adding mineral fertilizers	Removing through harvest more plants and animal nutrients than are replaced
	Accumulating shells and bones	Adding material in amounts toxic to plants or animals
	Accumulating ash locally	Altering soil constituents in a way to depress plant growth
	Removing excess amounts of substances such as salts	
Topography	Checking erosion through surface roughening	Causing subsidence by drainage of wetlands
	Land forming and structure building	Accelerating erosion
	Land leveling	Excavating
Climate	Adding water by irrigation	Subjecting soil to excessive insolation, to extended frost action, to expose to wind, to compaction
	Release of CO ₂ to atmosphere with possible warming trend in climate	Altering aspect by land forming
	Changing color of soil surface to change albedo	Clearing and burning off organic cover
	Removing water by drainage	
	Diverting wind	
Organisms	Introducing and controlling populations of plants and animals	Removing plants and animals
	Adding organic matter to soil directly or indirectly through organisms	Reducing organic content of soil through burning; plowing, overgrazing, harvesting, accelerating oxidation, and leaching
	Loosening soil by ploughing to admit more oxygen	Adding or fostering pathogenic organisms
	Removing pathogenic organisms, e.g., by controlled burning	
Time	Rejuvenating the soil by adding fresh parent material or through exposure of local parent material by soil erosion	Degrading the soil by accelerated removal of nutrients from soil and vegetation cover
	Reclaiming land from under water	Burying soil under solid fill or water

Source: Adapted from Bidwell & Hole,^[6] in which progressive and regressive influences were presented as beneficial and detrimental effects, respectively.

systems, such as no tillage, strip tillage, ridge tillage, and mulch tillage, which aims to reduce soil and water losses.^[7] Crop residue management designed to retain all or a portion of the previous crop's stalks on the soil surface is an important component of most conservation tillage. Maintaining an adequate level of organic materials by means of residue management, crop rotation, and manure is essential in soil management practices not only for providing major nutrients for crop growth but also for improving soil structure and reducing soil erosion.^[8] Without regular addition of adequate amounts of organic materials, the potential of erosion and leaching and gradual deterioration of soil physical properties increase. The strong positive correlation of organic matter content in soils with soil biodiversity has been well documented. Fertilizers and pesticides have led to a rapid increase of crop production, but wide use of agricultural chemicals also causes water pollution and soil degradation. Reduction of soil organic matter caused by replacing traditional organic fertilization through inorganic fertilizer is another negative influence on soil resilience. [Table 2](#) presents a more detailed description on soil management practices and their possible influence on soil's progressive and regressive pathways.

PRINCIPLES AND PRACTICES OF IMPROVING SOIL RESILIENCE

The basic principles of soil management to improve soil resilience are already well known. For agricultural soil management, they can be categorized as: 1) increase in soil organic matter content; 2) improvement in soil structure; 3) increase in soil biodiversity; 4) reduction of erosion rates; and 5) increase in nutrient capital and recycling mechanisms.^[9] Given the complexities of both soil-forming processes and socioeconomic causes of soil degradation, however, there is no single strategy or management policy for maintaining soil resilience. The rapid increase of agricultural production has been achieved by the intensification of land use, the use of motorized farm equipment, and the application of agrochemicals. These technological inputs frequently induce the loss of soil resilience and environmental pollution in many agricultural areas ([Table 2](#)).

New ideas have emerged for more sustainable soil management in both the developed and developing countries, replacing high-input agriculture.^[10] First, our improved understanding of the processes in the soil, water, and plant

Table 2 Major soil management practices and their possible influence on soil-forming processes.

Soil management	Management practice	Progressive influence on soil formation	Regressive influence on soil formation
Tillage	Conventional tillage	Increase aeration within plowed layers	Oxidative loss of organic matter
		Enhancing circulation of oxygen and water	Deterioration of soil structure
		Increase biological activity	Formation of subsurface plow pans
		Breaking surface and impermeable subsurface layers	Exposure of soil surface to raindrop impact, and water and wind erosion
		Increasing weathering rates	Reduction of plant diversity
	Conservation tillage (combined with residue management)	Increase of organic matter content in soil	Soil compaction (possibly in short term)
		Reducing erosion by increasing surface residue	Possible herbicide use
		Increase of biological activities	
		Reduced soil structure disruption (than conventional tillage)	
Maintaining organic matter and nutrients	Residue management (Crop residue mulching)	Protecting soil surface from raindrop impact	Reduction of soil temperature
		Reducing surface runoff	
		Increase organic matter content by the decomposition of residue	
		Increase biological activity	
		Less variation of soil temperature	

(Continued)

Table 2 Major soil management practices and their possible influence on soil-forming processes. (Continued)

Soil management	Management practice	Progressive influence on soil formation	Regressive influence on soil formation
Application of agricultural chemicals	Crop rotation (including cover and green manure crop)	Protecting soil surface by plant cover	Structural damage during harvesting of certain crops (e.g., potatoes, sugar beet)
		Increase organic matter input	
		Increase biodiversity in soils	
		Enhancing soil structure and stable aggregates	
		Enhancing nutrient balance	
	Organic fertilization (manure and compost)	Increase organic matter content in a short time period	Introduction of toxic chemicals and heavy metals
		Increase water retention capacity	Introduction of animal pathogens
		Promoting stable soil aggregates	Gaseous damage (e.g., ammonia) for certain plant species and microorganisms
	Shifting cultivation	Addition of nutrients into soils	Exposing soil surface to erosion processes
		Initial improvement of soil structure in heavy soils	Decrease of soil fauna population by heat
		Initial soil pH increases	Deterioration of soil structure through cropping
			Nutrient loss and soil acidification with cropping
Application of agricultural chemicals	Soil acidity adjustment (lime and gypsum application)	Reducing soil acidity	Decrease of infiltration rate with cropping
			Ionic imbalance of soil solution
	Inorganic fertilizer	Enhance stable soil aggregate formation	Selective leaching for certain ions (e.g., K^+)
		Increase of plant growth and crop yield	Reduction of soil organic matter replacing traditional soil organic management
		Enhance balance of solutes in soil	Increase of soil acidity by certain fertilizers (e.g., superphosphate)
			Nutrient imbalance and toxicity
Irrigation and drainage	Pesticide application		Possible loss of vital soil organisms
			Possible loss of vital soil organisms (e.g., earthworms, termites)
	Irrigation	Supplying water in soils	Accumulation of salts or alkali compounds in soil (in arid and semi-arid climate)
		Removing excessive salts	Deterioration of soil structure and consequent reduction of infiltration rate, when sodium is present
		Encouraging microbial activities	Increase of toxic elements (e.g., boron, selenium)
			Poor aeration caused by water logging
Mechanical erosion control	Drainage	Enhancing soil aeration	Rapid oxidation of organic matter
		Lowering the regional water table	Soil shrinkage and consequent surface lowering
	Contouring, terraces and waterways	Reducing erosion potential	Possible slope failure
			Removal of topsoil and expose of subsurface soil during construction

Note: This table is not intended to be exhaustive, it is also highly controversial for any generalization for all soil types.

ecosystem should be used for adapting management methods to the infinite variety of local conditions. Second, greater emphasis should be placed on efficiency of using soils, water, fertilizers, and plant resources instead of opening new fragile lands or relying on higher inputs. Finally, the joint efforts of resource scientists and the knowledge and skills of the local people should be used to address issues of soil management.

The first and second principles require more scientific and quantitative understanding of relationships between different soil management systems and long-term soil resilience. Soils are extremely complex media with many intrinsic feedback mechanisms, and the magnitude and degree of a given human intervention on soil resilience vary widely. It is also frequently recognized that a progressive influence of a human activity in one soil might be a regressive influence in other soils or the same type of soil in a different environment. Much information is available on how different soil management practices directly and indirectly regulate crop yields, but less is known about quantitative relationships between soil management and long-term soil processes that influence soil resilience characteristics. One important aspect of soil resilience studies is to develop appropriate restorative measures to improve degrading or already-degraded soils. This is especially important for many developing countries where cultivation of new land and advanced technological inputs are limited due to high population pressure and the lack of socioeconomic incentives.

Basic principles of enhancing soil resilience are known from many regions, but often those technical interventions are not available to farmers because of population pressures, limited natural resources, lack of secure land tenure systems, unfavorable macro-economic conditions, and poor national and international policies, etc.^[11] The processes of soil degradation are too locally specific to be effectively combated with the best land management developed elsewhere. The introduction of western farming techniques in many developing countries has been proven largely inadequate and sometimes disastrous for soil quality.^[10] Preserving and improving traditional land management techniques are increasingly considered the more sustainable land management system.^[12] Efforts to develop optimum sustainable soil management must include land users in both planning and implementation.

CONCLUSION

The rate of soil formation is slow, ranging from 0.001 to 0.4 cm a year,^[4] and the quality of such slowly forming soils is rapidly degrading due to inappropriate soil management in many parts of the world. Soil degradation trends give an alarming signal to the security of food production. Historically, the rapid increase of agricultural production has been achieved by the intensification of land use and the use of agrochemicals, but conservative soil management practices attract more attention than high-input agriculture in order to

reduce soil degradation and agriculture-related pollution. The basic principles for conservative soil management are how to reduce the destructive influence of soil management practices within the resilience potentials of soils and what is the most appropriate soil management to maintain or even improve soil resilience characteristics in given natural and socioeconomic conditions. Our improved understanding of the processes in soil, water, and plant ecosystems in relation to highly variable local environmental conditions is essential for these tasks. In addition, the joint efforts of resource scientists and the knowledge of the local people should be used to address issues of optimal local soil management. Soil resilience is a relatively new concept in soil science and land management studies, and the understanding of soil resilience and interaction with soil and land management are rather qualitative and descriptive. A high research priority should be given to develop objective and quantitative criteria of soil resilience, especially in relation to different soil-forming processes and also to assess the cause-effect relationship between different soil management practices and resilience.

Abstract

Soil resilience is an ecological concept being used to understand soil processes and their dynamics under stress. It refers to soil's capacity to resist change and restore itself when stress is removed and improved management systems are adopted. Soil resilience depends on inherent soil properties or soil quality, management and institutional factors, and climate. It can be measured for key soil properties and then aggregated to determine soil resilience class. Soil resilience has an important application to soil management for minimizing the risks of soil degradation and for restoring degraded soils. In view of the severity of soil degradation worldwide, the economic importance of soil resilience in maintaining soil quality and the multifunctions of soil cannot be overemphasized.

INTRODUCTION

Soil resilience, soil's ability to restore its productivity and environmental moderation/buffering capacity,^[1] is important because of the ever increasing risks of soil and environmental degradation due to anthropogenic activities. It is important to understand the factors and processes governing soil resilience and the techniques of measuring and modeling changes in it. The topic is more important and relevant because of at least five major global issues of the 21st century. These are as follows: 1) soil degradation and desertification; 2) accelerated greenhouse effect; 3) water scarcity; 4) land disposal of solid waste; and 5) agricultural sustainability. While all of these issues are influenced by soil resilience and quality, the global problem of soil degradation^[2] is an important issue that needs to be addressed.^[3] Soil degradation is also closely linked with the emission of greenhouse gases,^[4–6] water disposal,^[6] and water quality. Thus, an in-depth understanding of the mechanisms involved in imparting resilience to soils is a necessary prerequisite to identifying appropriate techniques for averting degradation and enhancing or maintaining soil resilience.

Soil quality, productivity, and environmental moderation capacity^[7] are the net balance between soil degradative processes and soil resilience (Fig. 1). In practice, soil quality is the capacity of the soil to perform a range of functions of value to humans. Important among these functions are as follows: 1) producing biomass; 2) filtering pollutants out of water; 3) buffering emissions of greenhouse gases; 4) moderating cycles of carbon (C), nitrogen, phosphorus, sulfur, water, and other elements; and 5) biodegrading contaminants. Soil resilience maintains or enhances these functions while keeping degradative processes under check and restoring soil's life-supporting and environmental cleansing

processes. Soil resilience can also decrease the risk of an accelerated greenhouse effect by C sequestration in stable microaggregates or deep incorporation in the soil profile; reduce eutrophication of surface water and contamination of groundwater by moderating its filtration and bioremediation processes; and facilitate achievement of agricultural sustainability by improving its life-supporting processes.

BASIC CONCEPTS AND DEFINITIONS

Applications of ecological concepts to soil science bring into focus several interrelated terms;^[8–12] some of these include the following:

Resilience: the capacity to restore.

Soil stability: the absence of change or constancy in soil quality.

Persistence: the length of survival.

Elasticity: the rate of restoration after perturbation.

Amplitude: the magnitude of change in soil quality from which restoration is possible.

These terms are subjective and to be useful in soil management and restoration, and it is important to operationalize them and develop methods to quantify their attributes.

There are two principal schools in relation to the concept of soil resilience.^[13] Per the first school, soil resilience refers to soil's capacity to restore itself.^[14,15] If not excessively degraded beyond the point of no return, soil, like any natural ecosystem, has the capacity to self-regulation and self-maintenance.^[16] Soil resilience, as per this school, is related to its: 1) filtration, detoxification, and transformation including bioremediation abilities; and

Fig. 1 Soil quality is the net effect of dynamic equilibrium between soil degradative and soil resilience processes.

2) its renewability, structural rejuvenation, and maintenance of a gene pool in soils.^[12,17] Per the second school, soil resilience refers to its ability to resist change^[2,18] or stability. According to this concept, therefore, soil resilience or stability is related to its buffering capacity. Although there may be some soils that can resist perturbation to a limit, most soils undergo change but may recover once the perturbation is removed.

Therefore, soil resilience may be defined as “soil’s ability to resist change and restore its quality following stress alleviation and adoption of improved management systems.” Land use and soil management are important to soil resilience.^[14] Similar to ecosystems, soils can also be grouped according to their resilience characteristics^[15,16] as follows:

High resilience: Soils that are not susceptible to degradation or are only slightly susceptible under extreme stresses. Some highly fertile and young soils come under this category, e.g., alluvial soils of the flood plains, Loess soils and Andisols on flat terrain, and Mollisols. These are dynamically stable soils.

Moderate resilience: Soils are moderately susceptible to degradative processes with continuous and intensive cultivation.

Slight resilience: These soils are easily susceptible to degradation and have low capacity to recover and restore.

Non-resilient: Such soils are easily degraded beyond the point of no return and cannot restore themselves. Some shallow soils on steep slopes are non-resilient against accelerated erosion. Similarly, a plinthic soil with a hardened layer at a shallow depth can be non-resilient. Non-resilient soils may be also called as fragile soils. These soils are easily destroyed in relation to their principal functions, e.g., productivity, environmental quality, social and aesthetic values, gene pool reserves, and support for engineering structures. Soil grouping according to this classification is shown in Table 1.

Susceptibility to degradation is just the reverse of soil resilience. However, the concept of “stability” cannot be applied to soils for agricultural use; e.g., plinthic (rocky) and gravelly soils may be highly stable but are not highly productive under intensive agricultural use. Such soils are

Table 1 Types of soil resilience in relation to agricultural land use.

Class	Type	Description	Soil order
1	Resilient	Highly responsive to science-based inputs; prime agricultural land, with a wide range of soil characteristics. These soils have a high buffering capacity.	Mollisols, Histosols, Inceptisols, Andisols, and other soils which are not easily degraded
2	Moderately resilient	These soils have fair to good agricultural potential and undergo changes in soil properties which can be restored with good soil management and science-based inputs. These soils respond to management. Changes in soil properties are modest, and soil properties can be restored by science-based management.	Oxisols, Ultisols, Alfisols, Entisol, and Aridisols
3	Slightly resilient	These soils have marginal or low agricultural potential, and the range of soil properties for productive use is narrow. These soils have only modest response to input. Critical limits for irreversible degradation are readily achieved.	Vertisols, Spodosols, and Psamments soils on steep terrain
4	Sensitive	These soils undergo drastic and adverse changes in soil properties, e.g., bulk density, infiltration, porosity, aggregation, and nutrient depletion, and are not suitable for agriculture. Examples include acid sulfate soils, shallow soils, soils on steep terrain, and ecologically sensitive regions. Intensive cultivation of poorly structured soils, draining of acid sulfate soils, and cultivation of marginal lands can lead to irreversible degradation by mismanagement or any intensive land use.	Sulfaquents, Psamments, and Entisols

Source: From Lal.^[19]

Fig. 2 Response to input of resilient and stable soils.

more suited for engineering (construction) than agricultural use. Soil is in dynamic equilibrium with its environment and management. A productive soil of high quality is not stable; it responds to management intensity. The term “management” is a broad-based concept, and “input” is a subset. The management may involve varying intensities of the same facets or different facets depending on the constraint to be alleviated. It is always undergoing a change and attains equilibrium at a level determined by its inherent properties and management (Figs. 2 and 3). Another important aspect of resilience and management is the economics of production. If the management intensity or the input is not economic, the soil loses its resilience for the specific use.

FACTORS AFFECTING SOIL RESILIENCE

Soil resilience is affected by a range of intrinsic soil properties (or endogenous factors) and external conditions (or exogenous factors) (Fig. 4). Soil quality constitutes an

Fig. 3 Temporal changes in soil quality as affected by soil resilience and management.

important endogenous factor and includes physical, chemical, and biological processes and entities of soil quality. Soil resilience decreases with increasing soil capability class.^[19] Important among exogenous factors are land use and management, socioeconomic and institutional factors, and climate. Soils of arid regions are slightly to moderately resilient, all other factors remaining the same. Factors that affect productivity, profitability, and the farmer’s ability to reinvest in soil improvement affect soil resilience. Productivity, sustainability, and environments are linked through soil resilience (Eq. 1, Fig. 5).

$$A_s = f(S_r, P, E)_t \quad (1)$$

where A_s is the agricultural sustainability, S_r is the soil resilience, P is the productivity, E is the environment, and t is the time. Resilient soils are productive, are easy to manage, and have a wide range of management and farming systems options for sustainable use.

ASSESSMENT OF SOIL RESILIENCE

Soil resilience is an ecological concept applied to soil. Operationalization of the concept depends on the development of methods to assess and predict soil resilience. Lal^[1,14] proposed that soil resilience may be assessed by measuring components outlined in Eq. 2.

$$S_r = S_a + \int_0^t (S_n - S_d + I_m) dt \quad (2)$$

where S_a is the antecedent condition, S_n is the renewability, S_d is the degradation, and I_m is the input or management. S_a is in relative terms and refers to conditions prior to subjection to a stress. The magnitude and sign of the term $(S_n - S_d + I_m)$ is important in defining soil resilience class. The application of Eq. 2 involves a separate assessment of the individual soil properties [soil organic C (SOC) content, top soil depth, available water capacity (AWC), nutrient reserves etc.] and then combines these as per a rating system.^[20] Developing an aggregate or composite S_r index may also involve statistical techniques including principal component analysis and cluster analysis. Soil resilience can also be computed for individual soil properties, such as structural resilience in relation to erodibility and compactability.^[21] Quantitative assessment of structural resilience is important in developing and adopting soil and crop management systems that minimize the risks of physical degradation, e.g., erosion, compaction, and crusting. Soil resilience may also be assessed for properties that affect other degradative processes, e.g., acidification and salinization.

Because it is a new concept in soil science, not much progress has been made in predicting soil resilience. Roza-nov^[13] proposed a physical model to predict soil resilience (Eqs. 3 and 4).

Fig. 4 Exogenous and endogenous factors and their interaction affecting soil resilience.

Fig. 5 Sustainability depends on productivity, environmental quality, and soil resilience.

$$S_r = \frac{dI/dx}{x} \quad (3)$$

$$S_r = -2I/x^2 \quad (4)$$

where S_r is the coefficient of soil resilience, I is the work or input required to change the soil property, x . Soil resilience of two soils or two land use systems is equal if a similar level of input is required to bring about the desired change in soil property, x .

SOIL RESILIENCE AND SOIL RESTORATION

Restoration of degraded soils and ecosystems is a high priority because global soil resources are finite and the world population is rapidly increasing at the rate of about 73 million per year. The soil quality depends on an optimal level of soil properties that a given soil needs to have in order to perform its functions satisfactorily. Therefore, the identification of appropriate techniques of soil restoration requires knowledge of the following: 1) soil resilience and 2) critical limits of key soil properties beyond which soil loses its resilience and becomes fragile and non-restorable for a given function. Key soil properties and their limits vary among soils and land use functions. However, important properties are rooting depth, SOC content, AWC, nutrient reserves, and soil structure as measured by aggregation and stability.

Knowledge of critical limits of soil properties is important because it may enable the land user to take soil out of a given land use before it becomes non-resilient or fragile. Similarly, an appropriate land use and management system may be chosen that will maintain or enhance soil quality, soil resilience, and soil stability. There are numerous

examples of soil quality and soil resilience enhancement by the choice of an appropriate land use system. Soils of the Machakos region of Kenya were severely degraded by the early to mid-1930s, and these badlands have been converted to productive farm land.^[22] Lessons learned from this example of soil resilience and land restoration can be applied to restore degraded soils elsewhere, e.g., the Himalayan–Tibetan ecosystem, Andean region, Central America, and the Caribbeans. Some soils of volcanic origin are highly stable and resist degradative processes.

Methods and degree of soil restoration or reclamation also depend on the land use or functions. With a change in soil resilience class, land use may also change; e.g., a soil capable of growing maize (*Zea mays*) can now grow only sorghum (*Sorghum bicolor*), or a soil capable of growing rice (*Oryza sativa*) can now only grow an upland crop. Therefore, the techniques and intensity of needed inputs depend on the land use or farming system intended.

There is a need to establish a link between the strategy or process of soil restoration and soil quality. This link is through key soil properties and the knowledge of their critical limits. Whether a degraded soil has been restored, through change in land use or management, can be determined through the analyses of key soil properties and their dynamics.

CONCLUSION

Soil resilience is an ecological concept being used to understand soil processes and their dynamics under stress. It refers to soil's capacity to resist change and restore itself when stress is removed and improved management systems are adopted. Soil resilience depends on inherent soil properties or soil quality, management and institutional factors, and climate. It can be measured for key soil properties and then aggregated to determine soil resilience class. Soil resilience has an important application to soil management for minimizing the risks of soil degradation and for restoring degraded soils. In view of the severity of soil degradation worldwide, the economic importance of soil resilience in maintaining soil quality and the multi-functions of soil cannot be overemphasized. However, additional research is needed to improve the concept and to enhance its application to sustainable management of soil and water resources.

Abstract

Processes of change in soils are relatively slow but common. In some cases, soils are improved so that their capacity for services increases. In most cases and particularly in developing countries, however, their services decrease. Some of the relevant processes are described briefly. Resilience is the property of the soil to resist changes in the level of services provided despite anthropogenic or environmental pressures. Because of resilience, soils can be degraded to some degree before their level of services declines significantly. Before reaching this level, degradation can be reversed and soils can be restored. Resilience also masks the degradation processes, particularly when the soils are deep and fertile, so that significant degradation may proceed unobserved.

INTRODUCTION

Soil is a substrate and a medium that provides many agricultural and non-agricultural services. Degradation is the broad term that describes the loss of soil value for a particular function. Soils are dynamic because the amount of soil at a particular location can increase or decrease, and the absolute and relative amounts of their components can change significantly. Some changes in soils are endogenous (e.g., weathering), while others are exogenous and are caused by animals (e.g., termite hills) and humans (e.g., reinforced drainage, deposition, and nutrient mining with crops). Cultivation on soil may cause it to degrade or to improve, depending on the management. From a global perspective, improvements are less common than degradation. Environmental conditions may also cause changes in soils.

Resilience, or resistance to change, varies greatly between soil types and is affected by climate and management practice. The degree of resilience and, hence, the period over which degradation can occur unnoticed is also quite variable, and so are the time and effort required to restore degraded soils. Typically, virgin soils converted to annual cultivation can be used for 3–30 years before the first sign of reduced function becomes apparent, after which degradation can take place for another 5–50 years until the soil is no longer economically productive.^[1–3] While restoration in general is technically feasible, the economic and sociological costs are often prohibitive.^[4,5] Preferably, interventions should be made early to mitigate degradative forces, taking advantage of inherent soil resilience to offset the restoration costs.

DEFINITIONS AND EXAMPLES

Resilience is the property of the soil to resist changes in the level of services it provides despite anthropogenic or environmental pressures. Degradation is the process by which soils change and its level of services declines. Anthropogenic degradation of soils has much accelerated in the past.^[4,6] Restoration is the process by which the soil is brought back to a prior condition, usually by improving its water and nutrient holding capacities.

Soils Provide Many Services

The services provided by soils are that they serve as a medium for agricultural crops, grasslands, and forests through which water and nutrients are absorbed, a medium to store and/or degrade pollutants, a place for recreation (golf!) and tourism, a place for temporary storage of excess water, generating water for streams and rivers by runoff from upland areas, and providing a surface for infrastructure and buildings. People enjoy several services simultaneously, but all of them are not important everywhere and at the same time. Soil degradation does not affect these services to the same extent. Hence, resilience with respect to these services can be very different. For instance, soils that are already mined for profitable cropping may still be of high value for infrastructure, recreation, or forestry. On the other hand, the service “generating water” need not be in conflict with “being a medium for crop production.”

Resilience and Lack of Degradation Are Not Identical

A soil may change considerably while its traditional service is not affected clearly, particularly in economic terms (e.g., erosion of a fertile and deep soil).^[7] In such cases, soil degradation may not appear to be a concern, and the need for soil and water conservation may not be recognized. If the changes continue, eventually leading to visible degradation, it will be more difficult to retain the same level of service, and the cost of restoration will escalate. In other cases, subtle changes in the soil may already have major consequences to its services (for instance, the addition of *Rhizobium* inoculum and small amounts of micronutrients can increase crop productivity). Fig. 1 shows examples of the resilience of different soil types to erosion. Other examples of resilience are discussed elsewhere.^[7-9]

Like any other object with mass, soils are resilient to change, meaning that their properties and components resist change in spite of external pressures that are constant or are sudden perturbations. An example is the alluvial soil of the Nile Valley, the agricultural function of which has remained unchanged for a thousand years or more. This example also shows that, in practice, resilience is a combined characteristic of the soil and its environment. Another example of resilience is the China Loess Plateau, where soils are very deep, and erosion of topsoil for hundreds of years has not diminished the productivity very much. Resilience is caused by: 1) the natural generation of soil from deeper layers, which occurs at a slow rate (<mm/yr) except for humid, tropical, volcanic soils, and alluvial and aeolian sedimentation (<cm/yr); 2) the weathering of rock minerals that provide all the nutrients for crops [phosphorus, potassium (K), micronutrients; a few kg/ha/yr] and biological nitrogen fixation (1–50 kg N/ha/yr); and 3) the buffering capacity of the soil mass. Degradation often goes hand in hand with transport of

soil, organic matter, and nutrients to another location where it may be beneficial (e.g., the Nile Valley clay) or detrimental (e.g., reservoir siltation). When soils change beyond their threshold of resilience, land users may be interested in restoration of the prior status of the soil. Restoration mainly refers to returning the capacity of the soil to support productive processes to the antecedent level, but not necessarily to the same physical, chemical, and biological state. While restoration is often technically feasible, economic and sociological conditions may not allow the process, and the land becomes barren. This is particularly pertinent to areas with low crop cover, such as in semiarid environments where crops are grown for short periods, and on infertile land where water harvesting and runoff redistribute soils and nutrients.

Sustainable soil and land management refers to situations where all biophysical, agronomic, economic, and sociological conditions for long-term farming are met simultaneously at the farm level.^[10,11] Soil resilience helps to overcome short periods of unsustainable land management. Such short-term benefits of resilience offer the advantage that, if appropriate management actions are taken, soil changes can be limited and the threshold of soil resilience is not exceeded.

EXTENT AND RATE OF DEGRADATION

Soil degradation is a widespread problem, to the extent that its productive uses have been diminished significantly. All continents suffer from loss in the capacity of soils to support agricultural crops, although some countries suffer more than others. An excellent description of the status of soil degradation was made by van Lynden and Oldeman.^[12,13] Yet it needs urgent updating, as the degraded land area is rapidly increasing where the resilience thresholds are surpassed ecologically and economically.^[3,4,14] For agricultural production, degradation implies that the yield ceiling is reduced, efficiency of inputs may be less (and hence the cost of production is increased), and the risk of crop failure escalates (Fig. 2).

Some degradation and erosion processes that put soil resilience to the test are elaborated below. Many technologies for soil and water conservation are relatively well known, but their adoption and adaptation depend heavily on whether the farmers' socioeconomic circumstances allow them to adopt the technology concerned. For instance, while terracing and alley cropping are known to be effective for controlling erosion, smallholder farmers often find such methods to be too expensive and labor demanding to match their resources. Willingness to follow soil conservation and restoration practices is particularly low when farmers do not own the land on which they farm and are not certain whether their investments will bring returns to their families.^[11] Therefore, lack of knowledge and land tenure and distance from markets, compounded

Fig. 1 Example of resilience of the service “relative crop yield” to erosion of different soil types.

Source: From Tengberg & Stocking.^[7]

Fig. 2 Consequences of soil degradation for the response of the relative crop yield to management.

Source: From Penning de Vries.^[14]

by opportunities for extensification and shifting cultivation, may lead smallholders in the tropics to pursue exploitative and degrading land management practices and to continue these beyond the limits of the resilience of their environment.

Resilience, Degradation, and Restoration

The degree of resilience of soils to the numerous processes of degradation (erosion, nutrient mining, salinization, compaction, surface sealing, etc.) varies widely, depending on the nature of the process and the characteristics of the soil and environment. Some of the important dimensions are outlined below, and the bibliography provides a comprehensive list of recommended literature on this subject.

Globally, erosion is one of the most important degradation processes.^[1,2,4,15] It involves transport of soil particles, organic matter, and soil nutrients, via flowing water or wind. Soil depth is a key factor determining resilience to these surface-erosive processes. In the humid tropics, water erosion can cause all the topsoil to be removed in one human generation. Wind erosion occurs in semiarid environments and contributes to desertification. Eroded soil can be valuable downstream, but it can also silt up waterways and reservoirs. The degree of resilience strongly depends on soil type and land management (Fig. 1). Restoration is generally not feasible, but halting the process is possible in the right socioeconomic environment with small trenches, and/or dikes^[7] provide good examples. The more the soil surface is covered by vegetation, particularly when early season (erosive) rains arrive, the higher the erosion is prevented. This generally calls for the use of perennial crops and mulches.

Another key degradation process is soil nutrient mining. Mining typically occurs when cropping removes more

nutrients than that added by the farmer as the soil generates.^[16] Resilience to this process depends on both capacity and intensity factors.^[9,17] If only one crop is harvested in 5–20 years and the other years are fallow (the slash-and-burn management system), weathering may provide as much nutrients as removed by the single crop, and the system is sustainable. But when there is insufficient space or time for fallow, which is common these days, then mining reduces soil organic matter (SOM) and its nutrients. In many developing countries, SOM levels have declined by 50% over the past, with concomitant reduction in pH and increased aluminum toxicity, and particularly with loss of nutrient holding capacity.^[18] Conversely, soil nutrient levels have risen in some areas of developed countries among others because of soil fertility transfer. Even when the SOM level remains constant, K stock can be reduced (e.g., intensive rice cultivation) and productivity decreased. Resilience of some soils in terms of nutrient and organic reserves is generally significant. For example, Vertisols may be cultivated for 20 years with good yields even without fertilizer application.^[19] Soil mining is often reversible, provided that the process has not gone too far, by adding legumes to the crop cycle and greater use of organic and inorganic fertilizers.^[17,20] Soil fertility can be viewed as a valuable natural resource that may be depleted to a certain degree and then replenished when conditions allow.

Erosion and loss of soil fertility are processes that tend to reinforce each other: less soil nutrients > less crops and less SOM > less soil cover > more erosion > less nutrients, and so on.

Salinization is a common soil degradation process in irrigated areas.^[2,3] Resilience to salinization is not a soil characteristic per se but relates to the climate and the management of water, trees, and crops. In some areas, dryland salinity occurs when deep soil contains salts that come to the surface due to insufficient rain infiltration or pumping of groundwater. Large parts of Australia and areas such as Northeast Thailand suffer from this phenomenon. Restoration is possible with appropriate management of water and vegetation in the landscape and when the problem has not progressed too far.

Compaction is the increase in density of soils, particularly because of heavy mechanical traffic. When soils are too compact, roots cannot penetrate; the soils absorb less water and nutrients, and production is reduced. Resilience to compaction depends much on the particle size distribution and cropping pattern. Compaction generally increases water runoff. Some soils are much less resilient and more sensitive than others. Restoration under conventional tillage may require heavy equipment for deep plowing.

Sealing of the surface has a similar effect; it may be caused by physical, chemical, and biological agents and can be eliminated with light equipment. However, maintenance of a continuous plant cover is needed to prevent it from reoccurring.

CONCLUSIONS

Resilience is an important intrinsic property of soils, but the extent to which it can prevent change in the level of services that a soil provides depends on the anthropogenic and environmental pressures exerted on it. Soils provide many services, and the resilience in providing these may be different. Moreover, the level of resilience is affected by degradation processes, such as erosion and soil nutrient mining. Resilience to change allows moderate levels of degradation after which restoration is still feasible. For the same reason, however, resilience masks consequences of degradation processes and leads to underestimation of the actual change.

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Soil respiration refers to the oxidation of organic materials by soil microorganisms, with generation of energy for microbial growth and maintenance, and production of carbon dioxide. The electrons needed for the oxidation of organic compounds originate, in most cases, from oxygen, which, therefore, is consumed by the respiration process. Because respiration is an attribute of all the life forms encountered in soils, it provides an integrative measure of soil biological activity and, appropriately, has extensively been used in soil biology research.

IMPORTANCE OF SOIL RESPIRATION

Soil respiration is a key driver of carbon (C) cycling in terrestrial ecosystems. While microbial decomposition of organic debris is essential to soil organic matter formation, the process also represents a major mechanism of C loss from soil systems. Global soil respiration is estimated at 68–100 Pg C year⁻¹,^[1] representing the second largest carbon dioxide (CO₂) flux in terrestrial ecosystems surpassed only by gross productivity.^[1,2]

As concerns over climate warming grow, it is becoming increasingly more important to document soil respiration in various ecosystems and to understand the biotic, environmental, and management factors affecting this process. Consequently, a tremendous amount of research has been dedicated to the study of soil respiration. It is not the goal of this contribution to provide an in-depth review of the extensive literature that this intensive research has generated. Several comprehensive reviews focusing on various aspects of soil respiration have been published.^[1,3–6] Instead, this entry is a cursory review of issues and knowledge of soil respiration addressed to the wider audience of soil scientists.

COMPONENTS OF SOIL RESPIRATION

The primary avenues of C entry into soil ecosystems are animal and plant debris (aboveground biomass, dead root tissues, and root exudates). Through the activity of soil microbes, these organic materials undergo decomposition with the more labile organic compounds readily converted into CO₂. The decomposition process also leads to the evolution of biochemically resistant secondary metabolites commonly referred to as humus or “stable” pools of soil

organic C (SOC). Depending on residue quality, soil, and climatic conditions, 10–20% of the residue-C returned to soil ends up in the humus pool.^[7] That pool also undergoes further decomposition but at much slower rates (20 to 50 times) than fresh residues. It is also important to note that not all the labile C fractions in soils are decomposed; however, through interaction with clays and inclusion within soil aggregates, some labile organic compounds become physically protected against microbial attack.

During photosynthesis, a fraction of the photosynthate C is translocated belowground. Some of the allocated C is consumed through respiration of root tissues (this is termed “autotrophic respiration”), while another fraction is released into the soil as root exudates, which could be rapidly decomposed by rhizosphere microbes. The decomposition of exudates and dead root tissue results in the production of CO₂, which, combined with autotrophic respiration, defines what is termed as “rhizosphere respiration.” “Total soil respiration,” which is reported in most studies, is defined as the sum of root respiration, litter decomposition, and stable SOC mineralization.

The contribution of rhizosphere respiration to total CO₂ production is variable, ranging from 10% to 90% of total soil respiration,^[4] with a generally higher contribution of root respiration to CO₂ flux in forests and grasslands than in agroecosystems mostly because of the difference in plant species and the duration of vegetative growth.

MEASUREMENTS OF SOIL RESPIRATION

CO₂ production is the most commonly used index of soil respiration intensity. Many procedures have been devised to measure CO₂ emission from soils, but the soil cover method is the most widely used approach.

An automated^[8] or a manually operated chamber of known dimensions (area, volume) is placed over the soil surface allowing CO₂ to accumulate inside. Soil respiration is expressed as the rate of CO₂ accumulation that is determined through: 1) measuring the amount of CO₂ absorbed by an alkaline solution (NaOH and KOH) placed inside the chamber; 2) regular sampling of the chamber headspace to determine change in CO₂ concentration using gas chromatography; and 3) interfacing the chamber with a flow-through system and an infrared gas analyzer for CO₂ determination. These procedures are sometimes combined with C labeling (administration of ¹³C- or ¹⁴C-labeled CO₂ to plants and monitoring the flux of labeled CO₂), root-exclusion techniques (comparing flux in areas with and without living roots) when assessing rhizosphere respiration.^[4] Bowen ratio/energy balance and eddy-covariance techniques have also been used and generally provide a more integrated estimate of flux over large areas.^[8] Review and comparison of these methods^[9,10] have shown that, within the bounds (e.g., duration of chamber closure, air flow speed) of a particular procedure, fluxes obtained with most methods are reasonably comparable. However, the alkali absorption method tends to overestimate fluxes probably because of an artificial lowering of CO₂ concentration at the soil surface by the alkali trap, resulting in an enhancement of respiratory activity, given reports^[10,11] of an enhancement of soil respiration at low CO₂ level.

CONTROLLING FACTORS OF SOIL RESPIRATION

Soil respiration is related to factors controlling the supply of organic carbon to soil microbes as well as factors controlling the abundance, distribution, and activity of the soil biota. Plant residue, dead roots, and root exudates constitute the primary sources of organic material entering soils. Studies conducted at both local and global scales have established the link between organic supply and soil respiration. Soil respiration was reported to increase nearly proportionally with the amount of residue added to soils.^[12] A summary report^[13] of CO₂ flux from 18 forest ecosystems within the Euroflux network concluded that ecosystem productivity, particularly the supply of young organic matter to fuel heterotrophic activity, was the main controller of soil respiration at these sites. A close relationship was also found between the net primary productivity (NPP is photosynthesis minus autotrophic respiration) of various natural and managed ecosystems and their mean annual soil respiration rates.^[1]

Temperature has been identified as the most important driver of soil respiration and several empirical models have been proposed to describe the relationship.^[1,5,6,14] The Q₁₀ coefficient, the relative change in respiration rate for a 10°C variation in temperature, is a commonly used index of the temperature sensitivity of soil respiration. It is derived from the equation $R_2 = R_1 Q_{10}^{(T_2 - T_1)/10}$, where R₁ and R₂ are rates

of respiration at temperatures T₁ and T₂, respectively. Typical Q₁₀ values reported in the literature ranged between 1.3 and 8.^[5] The temperature sensitivity of soil respiration varies inversely with temperature; i.e., at low temperatures, respiratory processes are highly sensitive to temperature variations but the sensitivity diminishes at higher temperatures.^[5,6,15,16]

Moisture is another controlling factor of soil respiration. A control of soil moisture on respiration is most often reported in semiarid regions where moisture deficit during the growing season is commonplace.^[17–19] Studies conducted in these regions have shown that soil CO₂ flux can increase by a factor of 2–5 between a wet and a dry year. A regional study^[18] of C dynamics across the U.S. Great Plains also concluded that, more than temperature and soil texture, soil moisture explained most of the regional variation in SOC decomposition. In a soil displacement experiment in Arizona^[15] in which respiration was monitored in mesocosms that were placed either upslope (more humid and cooler) or downslope to create a range of climatic conditions, it was observed that respiration increased by 40% under the mesic upslope conditions and decreased by 20% in mesocosms relocated in drier environments downslope. These findings further underscore the control of soil moisture on soil respiration in arid environments.

Several empirical models linking respiration to both soil temperature and moisture have been published.^[16,20] A synthesis of available data suggests that, under moist conditions, temperature is the main factor of soil respiration, while under dry conditions (a $\theta = 20\%$ is the proposed cutoff^[21]), temperature and moisture appear to have a multiplicative effect. This interpretation is consistent with reports of strong temperature control on respiration in studies conducted in humid regions,^[21–23] whereas greater effects of soil moisture are recorded in arid regions.^[15,17–19]

RESPIRATION AND CARBON SEQUESTRATION IN SOILS

An increase (1.4–5.8°C) in mean global temperature is predicted in the 21st century.^[24] The response of soil to climate warming has been the subject of considerable debate in the scientific literature. Reports of limited effect,^[3] acceleration,^[6] and adaptation^[25] of soil respiration in response to warming have been published. Given the linkage between temperature and respiratory C loss, one can infer that a warming of global climate would translate into increased transfer of C as CO₂ from soils into the atmosphere, thereby providing a positive feedback on climate warming.^[6] Assuming a Q₁₀ of 1.8, a 2°C increase in soil temperature would result in a 12% increase in global soil respiration (~9 Pg C year⁻¹), which is nearly three times the rate (3.2–3.4 Pg CO₂-C) of CO₂ accumulation in the atmosphere.^[24] On the other hand, it has been argued that increased temperature and atmospheric CO₂ concentration could enhance biomass production. Thus the rate of atmospheric CO₂

transfer into soils as plant biomass would increase.^[26] An analysis of these two conflicting scenarios^[5] concluded that stimulation of decomposition processes with climate warming will likely offset increase in NPP, thereby resulting in a net reduction in SOC storage. That analysis also suggested that changes in SOC storage will be slow and regionally variable with SOC gain in tropical region soils and net SOC loss in cooler regions.

EFFECTS OF MANAGEMENT AND SEASON ON SOIL RESPIRATION

The emission of CO₂ from soils is controlled by production and transport processes, which themselves are regulated by climatic and soil biophysical factors. Human intervention (management practices) can attenuate or enhance the effects of these factors on soil respiration through crop residue distribution, alteration of soil moisture and temperature regime, and disturbance of the soil biophysical environment.

Studies of soil respiration under optimum conditions in the laboratory have consistently found a larger labile C pool in soils amended with organic residue and soils under conservation tillage.^[12,23,27] They have also shown that both total and labile C pools are highly stratified in no-till (NT) soils compared with plowed soils.

We conducted laboratory incubation to determine the effects on soil respiration of tillage and soil disturbance as represented by soil sieving and erosion. In this evaluation, we compared C mineralization in runoff, sieved soil (< 2 mm) and in intact soil cores collected from research plots under NT and plow-till (PT) conditions for 38 years. Our data (Table 1) showed that after 200 days of incubation,

C mineralized in the sieved soil exceeded that in the core samples by 1153 and 146 mg C kg⁻¹ soil in the NT and PT soils, respectively. These figures also provide a clear indication of how disturbances (sieving and erosion) contribute to the release of protected C in NT soils. In conjunction with the high mineralization rate of runoff C, these data also indicate that a large fraction of the C that accumulates in soils through conservation tillage is labile and could be easily lost with soil disturbance.

Unlike the consistently positive effect of tillage on soil respiration observed with incubation studies, field-scale investigations of CO₂ emission in relation to tillage practices have yielded mixed results. Published data include comparable,^[19,27] higher^[19] and lower^[22,28] CO₂ emission from NT soils compared with plowed soils. Other studies^[23,29] have also reported a 10–20% lower CO₂ emission from NT soils compared with plowed soils. These variable results suggest that at the field-scale level, the effect of tillage on CO₂ flux is governed less by labile C availability but rather by soil moisture and temperature. Higher CO₂ emission from plowed soils has been linked to higher soil temperature.^[22]

As the driving variables (temperature, moisture, and organic substrates) vary with time, it follows that soil CO₂ emission exhibits strong seasonal variability with CO₂ flux maxima often recorded during late spring and summer and lowest fluxes generally occurring in the autumn.^[12] Overwinter soil respiration has generally been overlooked. However, several studies^[12,28] have shown that between 4% and 20% of the annual CO₂ emission occurs during the winter to spring-thaw period.

CONCLUSION

The oxidation of organic compounds to CO₂ by soil microbes is a major pathway of C loss in terrestrial ecosystems. Microbial processing of animal and plant residues is essential for the incorporation of biomass-C into SOC pools. These parallel processes (mineralization and biomass conversion) suggest that land use and management practices that optimize residue input and decomposition and that minimize respiratory C loss, likely lead to net increment of soil C stocks in the long run. In this synthesis of the literature, various drivers of soil respiration have been identified. Among them, soil temperature (e.g., with residue on soil surface) and soil disturbance (e.g., conservation tillage) are factors that can be managed to achieve C sequestration in soils. However, when soil respiration is placed in the context of climate warming or other anthropogenic disturbances such as N deposition, it appears that changes in soil respiration will be controlled by complex interactions between several direct and indirect factors. A synthesis of the literature on that issue reveals several schools of thought. These divergent views not only demonstrate the biogeochemical complexity of C flow in

Table 1 Organic carbon mineralization as affected by tillage practice and disturbance.

Tillage	Material incubated ^a	Duration of incubation (days)	CO ₂ evolved (g C kg ⁻¹ soil)
NT, 38 years	Core (5-cm diam, 5-cm L)	200	0.48 ± 0.09
Sieved soil (< 2 mm)	200	1.63 ± 0.02	
Runoff	100	12.4 ± 2.8	
PT, 38 years	Core (5-cm diam, 5-cm L)	200	0.34 ± 0.08
Sieved soil (< 2 mm)	200	0.22 ± 0.06	
Runoff	70	6.7 ± 2.8	

Note: Values are the means ± standard deviation of six observations.

^aAll materials were collected from a Crosby (fine, mixed, mesic Aeric Ochraqualf) soil at 0–10-cm depth. Triplicate cores and sieved soil (20 g) samples were incubated in a 450-ml jar and in 160-ml serum bottles, respectively. Details regarding runoff generation and incubation are available elsewhere.

Restoration Ecology

Richard Hobbs

Murdoch University, Murdoch, Western Australia, Australia

Abstract

The term “ecological restoration” covers a wide range of activities involved with the repair of damaged or degraded ecosystems. An array of terms has been used to describe these activities including restoration, rehabilitation, reclamation, reconstruction, and reallocation. Generally, restoration is used to describe the complete reassembly of a degraded system to its undegraded state, while rehabilitation describes efforts to develop some sort of functional protective or productive system on a degraded site.

INTRODUCTION

Restoration ecology is the science behind ecological restoration, which covers a wide range of activities involved with the repair of damaged or degraded ecosystems, and is usually carried out for one of the following reasons:

1. To restore highly disturbed, but localized sites, such as mine sites
2. To improve productive capability in degraded production lands
3. To enhance nature conservation values in protected landscapes
4. To restore ecological processes over broad landscape-scale or regional areas.

Ecological restoration occurs along a continuum from the rebuilding of totally devastated sites to the limited management of relatively unmodified sites. Restoration aims to return the degraded system to some form of cover that is protective, productive, esthetically pleasing, or valuable in a conservation sense.^[1] A further tacit aim is to develop a system that is sustainable in the long term.

The conceptual basis of restoration ecology has developed rapidly.^[2–6] The term “ecological restoration” covers a wide range of activities involved with the repair of damaged or degraded ecosystems. An array of terms has been used to describe these activities including restoration, rehabilitation, reclamation, reconstruction, and reallocation. Generally, restoration is used to describe the complete reassembly of a degraded system to its undegraded state, while rehabilitation describes efforts to develop some sort of functional protective or productive system on a degraded site. In addition, some authors also use the term “reallocation” to describe the transfer of a site from one land use to a more productive or otherwise beneficial use. Here I will follow^[1] and use the term restoration to refer broadly to activities that aim to repair damaged systems, although the other terms are used as above in particular examples.

Restoration ecology involves a number of interconnected activities, as summarized in Fig. 1.

DYNAMIC SYSTEMS AND RESTORATION GOALS

Ecosystem characteristics, which may be used when considering restoration goals, include as follows:^[1]

1. Composition: species present and their relative abundances
2. Structure: vertical arrangement of vegetation and soil components (living and dead)
3. Pattern: horizontal arrangement of system components
4. Heterogeneity: a complex variable made up of components 1–3
5. Function: performance of basic ecological processes (energy, water, nutrient transfers)
6. Species interactions: includes pollination, seed dispersal, etc.
7. Dynamics and resilience: succession and state-transition processes, recovery from disturbance.

Ecosystems are naturally dynamic entities, and hence the setting of restoration goals in terms of static compositional or structural attributes is problematic. Often, past system composition or structure is unknown or partially known, and past data provide only static snapshots of system parameters. Existing undegraded reference systems can therefore act as potential reference systems against which the success of restoration efforts in degraded systems can be measured. An alternative approach is to recognize explicitly the dynamic nature of ecosystems and to accept that there are a range of potential short- and long-term outcomes of restoration projects. The aim should be to have a transparent and defensible method of setting goals for restoration, which focuses on the desired characteristics for the system *in the future*, rather than in relation to what these were in the past. Where it is impossible or extremely expensive to restore composition and structure, alternative goals

Fig. 1 Processes involved in ecological restoration.
Source: From Hobbs.^[7]

are appropriate. These may aim to repair damage to ecological function or ecosystem services, or to create a novel system using species not native to the region or those suited to changed environmental conditions.

Goal setting thus becomes an extremely important component of the restoration process. Goals for a particular site, or more broadly for a landscape, will need to be determined iteratively by considering the ecological potential for restoration and matching this against societal desires. This argues for an adaptive approach to restoration, which garners ecological knowledge from as many sources as possible (including on-ground practitioners), and uses this knowledge to develop ecological response models that can indicate the likely outcomes of restoration activities. Which of the restoration options is taken up is decided on the basis of the stakeholder expectations and goals, and the extent to which it is implemented depends on the degree of financial and resource input from various sectors, including individual investment and public subsidy or incentives.

RESTORATION OPTIONS

Arriving at clear restoration goals requires a clear picture of the restoration options available for a particular site, landscape or region. Restoration activities need to be prefaced by a rigorous assessment of the current state of the particular system or landscape, and the underlying factors leading to that state. Once this has been achieved, a clearer picture of the necessary restoration activities is possible, and a range of restoration options can be determined (Figs. 2 and 3).

Ecological restoration is required only where the system's resilience has been diminished in some way, or where

Fig. 2 Mine site in *Eucalyptus marginata* forest in Western Australia, following soil removal for extraction of alumina.

the normal recovery processes are too slow to achieve management goals within a desirable time frame. Restoration requires that the stressors acting on the system are removed and may also involve replacing components that have been lost during the degradation of the system. Degrading processes can result in a variety of ecosystem responses, depending on the intensity, duration, and scale of the impact, and on which system components and processes are affected. Stressors, which impair the processes of resource capture by plants (e.g., soil erosion, alteration of hydrology), are likely to have much greater impacts than stressors that remove or damage plants or consumers (e.g., pathogens or unsuitable fire regime).

A general feature of many systems seems to be the potential for the system to exist in a number of possible states, and the likelihood that restoration thresholds exist, which prevent the system from returning to a less-degraded state without the input of management effort.^[1] It has been suggested that two main types of such thresholds are likely, one that is caused by biotic interactions and the other

Fig. 3 Mine site in *Eucalyptus marginata* forest in Western Australia, following restoration involving soil ripping, topsoil replacement, and seeding with native species.

caused by abiotic limitations.^[6] If the system has degraded mainly due to biotic changes (such as grazing-induced changes in vegetation composition), restoration efforts need to focus on biotic manipulations that remove the degrading factor (e.g., the grazing animal) and adjust the biotic composition (e.g., replant desired species). If, on the other hand, the system has degraded due to changes in abiotic features (such as through soil erosion or contamination), restoration efforts need to focus first on removing the degrading factor and repairing the physical and/or chemical environment. In the latter case, there is little point in focusing on biotic manipulation without first tackling the abiotic problems.

The above argument is akin to ensuring that system functioning is corrected or maintained before questions of biotic composition and structure are considered. Considering system function provides a useful framework for the initial assessment of the state of the system and the subsequent selection of repair measures.^[8,9] Where function is not impaired, restoration can legitimately focus on composition and structure as parameters to be considered when setting goals.

MEASUREMENTS OF SUCCESS

There have been numerous attempts to provide categories of assessment that will contribute to a picture of the "healthy ecosystem," which have varying degrees of ease of measurement. Biological potential inventory is probably the earliest form of ecosystem assessment, typified by the species list. Although this can be extremely useful for assessing conservation status and is greatly improved by measurements over time, it often does not get to the basics of what is causing the degradation, rather simply reflecting the magnitude and direction of its effect.

More complex measurements of biological integrity can assess food-web complexity and the development of symbiotic relationships. However, difficulty of assessment increases greatly. Measurements relating to ecosystem function can include estimates of production, standing crop, mass balance, and mineral cycling pools and rates. The problem with all these measures lies in determining what the target should be, in relation to the problems discussed above concerning reference systems. More generally, indicators of soil quality improvement with restoration can include factors such as pH, organic matter content,

physical properties such as texture, erodibility, compaction, water-holding capacity and drainage, and chemical properties such as toxicities associated with heavy metals and other contaminants, and the availability of nitrogen, potassium, and phosphorus.^[10]

Measures of success have to be linked back to the clear definitions of goals for restoration. Assessment processes can be complicated and expensive, and if they are too complicated or expensive they will not be carried out. There is no point in assessing something unless it relates to specific goals. These goals can be set in relation to data on the preexisting ecosystem, or in relation to adjacent systems, or can be settled on by discussion with stakeholders about what may be possible and desirable on the site.

Restoration: Success and Completion Criteria

Sam C. Ward

Bicton, Western Australia, Australia

Abstract

Restoration of a disturbed area entails restoring the land, so that the predisturbance conditions are replicated as closely as possible with all the area's environmental values intact. The term generally applies to the restoration of native ecosystems. Any project that aims to repair degraded land must have clear goals. This entry refers to success and completion criteria for restoration. It includes a case study of the restoration of a eucalyptus forest after mining to demonstrate the level of success and the completion criteria that have been used in a major project that is restoring around 500 ha of forest each year.

INTRODUCTION

Restoration of a disturbed area entails restoring the land, so that the predisturbance conditions are replicated as closely as possible with all the area's environmental values intact.^[1] The term generally applies to the restoration of native ecosystems. Approaches to success and completion criteria vary in different countries. In the United States, the system relies on vigorously enforced regulation, whereas in other countries, including Australia, a more flexible system of guidelines for rehabilitation or restoration is used.

Any project that aims to repair degraded land must have clear goals. Without goals, there is no way of determining whether a project is successful. This entry refers specifically to success and completion criteria for restoration. It includes a case study of the restoration of a eucalyptus forest after mining to demonstrate the level of success and the completion criteria that have been used in a major project that is restoring around 500 ha of forest each year.

Restoration infers that some aspects of the following characteristics of the area are restored (Adapted from Hobbs and Norton^[2]):

1. Composition: species' presence and their relative abundances;
2. Structure: vertical arrangement of vegetation and soil components;
3. Pattern: horizontal arrangement of system components;
4. Heterogeneity: a complex variable made up from the three variables above plus heterogeneity of soil characteristics, litter distribution, etc.;
5. Function: performance of basic ecological processes (energy, water, and nutrient transfers); and
6. Dynamics and resilience: successional processes, recovery from disturbance.

Debate surrounds the use of reference ecosystems against which restoration projects should be assessed. Pickett and Parker^[3] consider that choosing a reference state or system is a "trap" and a "pitfall" to be avoided. They make the point that natural systems are dynamic, rather than static and predictable, and therefore contend that it is futile to try to recreate an ecosystem, as it was at a particular time. However, Aronson et al.^[4] argue that for any restoration project, there must be a reference against which the results of the project can be assessed. Aronson et al.^[5] define an "ecosystem of reference" as "some standard of comparison and evaluation, even if the choice is somewhat arbitrary." Restoration after coal mining in the United States uses land that is representative of the premining abiotic and biotic conditions and large enough to withstand natural and man-induced perturbations as reference areas.^[6] Whether or not an "ecosystem of reference" is adopted, some of the desirable characteristics of the target ecosystem must be defined and measured in the developing restored ecosystem before restoration can be considered successful.

ENVIRONMENTAL INDICATORS

It is obvious that not all of the characteristics of a restored ecosystem can be measured. What needs to be measured are a number of indicators that summarize the characteristics of systems and make it possible to gauge the general status of a system. Environmental indicators are physical, chemical, biological, or socioeconomic measures that best represent the key elements of a complex ecosystem or environmental issues.^[7] The "Holy Grail" of restoration ecology is one measure that integrates all aspects of ecosystem function and structure into one or a small number of "one-off" measurements. Unfortunately, a single indicator or index (a mathematical combination of a number of indicators) is unlikely to be able to represent anything as complex as the successful restoration of an ecosystem.

For a general rehabilitation project, where the object is to return a stable, vegetated landform that does not replicate any existing predisturbance ecosystem, relatively simple methods to judge rehabilitation success may be appropriate. For example, a system called Ecosystem Function Analysis (EFA) has been developed in a project funded by the Australian mining industry.^[8] EFA consists of the following three modules: landscape function analysis, vegetation development, and habitat complexity. The system conceives rehabilitation as being land degradation in reverse with successful rehabilitation becoming more able to regulate the movement, and minimize the losses, of vital ecosystem resources such as water, topsoil, nutrients, and organic matter. This method offers a simple methodology for assessing the sustainability of a rehabilitated ecosystem and is especially useful for small or “one-off” rehabilitation efforts where financial and other resources may be limited.

For large restoration projects, especially those where rehabilitation is progressive over a long period, a more intensive assessment effort is required that can assess progression toward a specific end. The assessment should also be able to give feedback, so that restoration procedures on areas that are still undergoing rehabilitation can be continually improved.

General criteria for assessing all restoration projects have not been established. A large number of potential indicators of restoration success could be adopted. The challenge for the managers of any restoration project is to select the most relevant indicators for them to make decisions on the management of a restored area. The indicators ideally should be simple, repeatable, reliable, affordable, sensitive, and able to be aggregated with other measures. Indicators that can be measured repeatedly are valuable, as a time series of measurements allows the trajectory of the ecosystem to be visualized. “One-off” measurements often do not provide an accurate representation of a dynamic ecosystem.

Aronson et al.^[5] proposed a number of “vital ecosystem attributes” that may serve as indicators of ecosystem structure and function. Examples of attributes of ecosystem structure are perennial species richness, annual species richness, total plant cover, aboveground phytomass, beta diversity, life-form spectrum, keystone species, microbial biomass, and soil biota diversity. Examples of attributes of ecosystem function are biomass productivity, soil organic matter, maximum available soil water reserves, coefficient of rainfall efficiency, rain-use efficiency, length of water availability period, nitrogen-use efficiency, micro-symbiont effectiveness, and cycling indices.

Hobbs and Norton^[2] suggested that these attributes were a good starting point for developing a list of parameters (indicators) to be measured to assess rehabilitation development and success. Smyth and Dearden^[6] proposed a two-stage approach to measuring rehabilitation success. The first stage is successful landscaping and soil reconstruction. Soils hold some of the most important non-renewable

resources of an ecosystem,^[9] and the depth of soil available for root growth is a fundamental determinant of which plant species will establish and survive. The development of a stable soil with suitable physical and chemical characteristics is a basic requirement for successful restoration. The second stage is the evaluation of functional capacity and long-term successional trends. Ecosystems may not develop in an ordered and gradual manner but may undergo rapid transitions between different metastable states.^[10,11] The dynamic nature and possible multiple metastable states of natural ecosystems mean that the target values for “vital ecosystem attributes” will need to be defined with a mean and a variance. The values of the combined set of parameters in rehabilitated areas can then be compared against the target values or the natural variability found in “reference ecosystems” to provide a “scorecard” for the rehabilitation project.^[2]

COMPLETION CRITERIA

Completion criteria have been defined in a number of ways^[12,13] but can be considered as qualitative or quantitative indicators against which a restoration or rehabilitation project can be assessed, so that responsibility for the area can be relinquished. They may include physical, biological, water quality, and safety indicators. It is generally accepted that completion criteria need to be developed on a site-specific basis.^[13,14] This can be difficult and time-consuming and requires a detailed knowledge of the ecosystem being restored. For example, Smyth and Dearden^[6] present a flowchart of reclamation planning, implementation, and monitoring for surface coal mine rehabilitation in the United States. Identifying the major impediments to restoration can help in selecting the appropriate indicators.

Completion criteria for land disturbed by mining, construction, or other human-induced degradation serve two main purposes. First, they give both the landowner or land manager (e.g., private citizens or companies, or local, state, or federal government departments) and the parties responsible for the disturbance (e.g., mining companies) a clear direction for restoration. Second, they describe the state of the restored area and surrounding lands that were influenced by the disturbance at which any financial obligation or legal responsibilities can be relinquished by those responsible for the disturbance.

CASE STUDY

An example of established completion criteria comes from the restoration of the jarrah (*Eucalyptus marginata* Donn ex Smith) after bauxite mining in Southwest Australia, where Alcoa World Alumina, Australia, mines and restores around 500 ha of jarrah forest each year. Alcoa’s rehabilitation objective is “to establish a self-sustaining jarrah forest ecosystem planned to enhance or maintain water,

Table 1 Criteria used by Alcoa World Alumina to assess the establishment, development, and growth of the flora on rehabilitated bauxite mines in Southwest Australia.

Criteria and intent	Timing	Guidelines for acceptance	Standard	Corrective action
Has the area been deep ripped?	During rehabilitation	All ripping must prevent water runoff and soil erosion Rielines must not discharge water into forest Ripping must be according to criteria established	No uncontrolled water runoff or soil erosion	Areas of unacceptable ^a erosion to be reworked and erosion control methods applied
Have areas of caprock been fractured by blasting or ripping?	During rehabilitation	All caprock should have been broken by ripping or blasting. Small areas less than 0.1 ha are acceptable	No area greater than 0.1 ha has unbroken caprock	Areas of caprock not broken over 0.1 of a hectare must be broken and revegetated
Is there an adequate cover of topsoil?	During rehabilitation	Topsoil should be spread across the whole rehabilitated area. Areas (less than 0.5 ha) not receiving topsoil are acceptable provided these areas do not exceed 10% of the rehabilitated area	Topsoil is spread over a minimum of 90% of the rehabilitated area	Topsoil or additional seed/fertilizer may be spread over the bare areas
Are there adequate numbers of both jarrah and marri?	9 Months after rehabilitation	Rehabilitated areas must have a stocking rate which will meet proposed land use	An average of 1300 stems ha ⁻¹ to be present at 9 months over 65% of the pit, of which at least 200 stems are marri to ensure that dieback does not devastate the site	Rehabilitated areas not meeting the standard will be re-planted as required
Is there an adequate legume content?	9 Months after rehabilitation	Areas to have at least one legume/m ² . Areas up to 0.5 ha not meeting the standard are acceptable provided they are not greater than 10% of the pit	1 legume m ⁻² based on 9-month establishment monitoring	Areas will be scarified and seeded with legumes
Are there any bare areas other than sumps greater than 0.5 ha?	9 Months after rehabilitation	As above	There are no areas greater than 0.5 ha with less than 1 legume m ⁻²	Areas of 0.5 ha or greater not stocked at the rate of 1 legume m ⁻² to be reseeded the following autumn
Is there an appropriate species richness?	15 Months after rehabilitation	Areas to have a representative number of forest species present	Minimum of 50% of species in forest controls based on 15-month monitoring	Areas may need to receive additional seed. Sites to be scarified and seeded
Are there adequate stocking rates of eucalypts and understory species capable of regenerating after a wildfire?	Approximately 10 years after rehabilitation	Guidelines for acceptance still being established based on fire recovery patterns	The site is capable of recovering from a wildfire	Treatments may be needed such as reseeded or thinning of areas
Are there adequate numbers of both jarrah and marri?	Approximately 15–20 years after rehabilitation	Numbers need to be adequate to meet the designated land use. Tree crowns need to be healthy, of suitable density and in proportion to their tree height	Minimum of 300 stems ha ⁻¹ with the potential to produce trees with sawn timber potential	A thinning may be required

^aUnacceptable erosion is that which poses an accident hazard to a walking human or could lead to uncontrolled water discharge from a pit.Source: From Elliott, Gardner, et al.^[17]

timber, recreation, conservation and/or other forest values.” The restoration process involves landscaping, soil return, ripping, seeding, and fertilizing. Restoration is described more fully by Nichols et al.^[15] and Ward et al.^[16]

According to Elliott et al.^[17] the restored areas must:

1. Meet land use objectives.
2. Be integrated into the landscape.
3. Exhibit sustainable growth and development.
4. Be able to be integrated with forest management.
5. Ensure that vegetation is resilient to disturbance.

Jarrah forests may take several centuries before attaining maturity, much longer than it is practical for Alcoa to maintain responsibility for the area. The company developed completion criteria, with input from all the stakeholders, that can be measured during restoration or relatively early in the development of the restored ecosystem. Alcoa's completion criteria consist of both assessments of the quality of the restoration procedures and indicators of restoration development and success, similar to the two-stage strategy proposed by Smyth and Dearden.^[6] Any impediments to successful rehabilitation need to be identified as early as possible. Early identification of problems may allow them to be remedied, or for rehabilitation procedures to be changed in subsequent years.

Restoration of the jarrah forest after mining demands that tree roots have access to water stored deep in the soil profile, propagules of a wide range of species are available, adequate nutrients are available, and soil conditions are suitable for the establishment and growth of the flora. It is impossible to measure all the indicators of ecosystem function or structure that may be of interest on every hectare of restored land. Different indicators are measured at different times after the restoration process. Indicators are measured at different intensities for a number of reasons, not the least of which is cost. Examples of the criteria used to assess the establishment, growth, and development of the flora are given in Table 1. The establishment of eucalypts and legumes is assessed each year on transects that cover all of that year's rehabilitation. Plant species richness is measured on randomly located plots within each 2–4 ha of 15-month-old rehabilitation.

When all these criteria are met, monitoring and research that have been carried out in the past give a degree of confidence that the ecosystem is on a trajectory leading to a sustainable, diverse jarrah forest that does not require extra management costs, above those required for the native forest. Many examples of measures of ecosystem structure or function on Alcoa's bauxite mines of various ages, which are similar to, or trending toward, values found in the unmined jarrah forest, have been published. Examples include soil nitrogen,^[18,19] litter production,^[18,19] litter nutrient content,^[18,19] total ecosystem nitrogen,^[18,19,20] microbial

biomass and microbial quotient,^[21,22] botanical diversity (species richness),^[23,24] the abundance of VA mycorrhiza,^[25–27] depth to the water table,^[28] and the resilience to fire of the major plant species.^[29,30]

Rice Paddies: Methane Emissions

Ronald L. Sass

Department of Ecology and Evolutionary Biology, Rice University, Houston, Texas, U.S.A.

Abstract

Methane (CH₄) emission from rice fields is the result of soil bacterial processes, i.e., production in flooded anaerobic microsites and consumption (oxidation) in aerobic microsites. The flooding of rice fields promotes the anaerobic fermentation of carbon sources supplied by the rice plants and other incorporated organics, resulting in the formation of CH₄. CH₄ reaches the atmosphere primarily through a gas-conducting system in the rice plants and by the ebullition of gas bubbles and diffusion. The process is governed by a complex set of parameters linking the physical and biological characteristics of flooded soil environments with specific agricultural management practices.

INTRODUCTION

Methane (CH₄) is an important greenhouse gas with a global warming potential approximately 21 times that of carbon dioxide. Of the agricultural sources that may account for as much as 40% of the total annual emission of atmospheric CH₄, a significant portion is contributed by rice cultivation. As one of the major crops of the world, rice accounts for approximately 23% of its per capita calorie intake. Modern estimates suggest that 50 ± 20 teragrams (Tg)/yr (1 Tg = 1 million metric tons) of CH₄ is emitted from global rice paddies. CH₄ is produced under anaerobic conditions generated in flooded rice fields. Irrigated rice fields account for 51%, rainfed fields for 27%, and deep-water fields for 8% of the world's total harvested rice lands. Dry upland rice lands (14%) are not flooded for any significant duration of time and do not produce CH₄.^[1]

FACTORS AFFECTING CH₄ EMISSIONS

Diel and Seasonal Patterns of CH₄ Emission

A positive dependence on temperature is observed in the diel pattern of CH₄ emission in rice fields and in incubation studies.^[1] Seasonal variations in CH₄ emission from rice paddies are more complex and differ among studies. Growth-seasonal CH₄ fluxes observed in temperate rice fields show a general correlation with temperature but respond primarily to seasonal trends in plant development and carbon (C) inputs. From negligible values at the beginning of the season, CH₄ emission gradually increases during the vegetative phase correlating with increasing plant biomass and peaks near panicle differentiation, a period of rapid root development. Emission remains relatively constant during the reproductive stage but may decrease during

late grain filling because of root degradation. Prior to the end of the season, a second emission peak may be observed. This late-season increase in emission can be attributed to an increase in soil C substrate due to accelerating leaf and root senescence.^[1] The addition of readily degradable C, such as rice straw, before planting results in an increase in the early-season CH₄ emission. The decomposition of the straw may also result in an enhanced or additional early-season emission maximum.^[1]

Photosynthetic Activity

In irrigated tropical rice paddies with double cropping, both CH₄ emission and rice grain yields are consistently higher in the dry season than in the wet season.^[2] One interpretation of this finding is that higher photosynthetic rates during the sunnier days of the dry season lead to larger amounts of C available to methanogenic bacteria and, consequently, greater production and emission rates of CH₄. Seasonal rates of CH₄ emission and rice grain yield have been positively correlated with accumulated solar radiation.^[3] A 1% increase in accumulative solar radiation is accompanied by a 1.1% increase in CH₄ emission and a 1% increase in rice grain yield. These findings are consistent with the hypothesis that solar radiation and hence photosynthetic activity of the rice plant correlate with CH₄ production and grain yield through the partitioning of non-structural carbohydrates to the root system and grain panicle.

Organic Amendments

Organic amendments of flooded rice paddies increase both CH₄ production and emission to the atmosphere. The amount of CH₄ emitted as a result of organic soil

amendments depends greatly on the amount and condition of readily available decomposable C contained in the treatment. CH₄ emission with incorporated rice straw has been found to be higher than that from either compost or mineral-fertilized plots.^[4] The effect of incorporating green manure is even more dramatic.^[5] Schütz et al.^[6] observed a 2.4-fold increase over control values with added rice straw. Cicerone et al.^[7] observed increases from a control value of 1.4 up to 58.18 g CH₄ m⁻² yr⁻¹ with added straw, a factor of over 40 times. Wassmann et al.,^[8] investigating the effect of fertilizers on CH₄ emission rates in Chinese rice fields (Hunan Province), found that the rate of increase in CH₄ emission depended on the total amount of organic manure applied. A single dose of organic manure increased the emission rates by the factors of 2.7 to 4.1, as compared with fields without organic manure. In field studies in the Philippines, Denier van der Gon and Neue^[9] found that fields treated with green manure applied at a rate of 22 t ha⁻¹ emitted over twice as much CH₄ as fields in which the application rate was 11 t ha⁻¹. Studies indicate that CH₄ emission enhancement due to added straw depends on soil type. In a study conducted in Bali,^[10] total amounts of CH₄ emitted during the rice growth period were 2.6–3.3 g m⁻² with applied chemical fertilizers compared with 3.9–6.8 g m⁻² with rice straw application in Alfisol plots, and 4.2–5.8 g m⁻² with applied chemical fertilizers compared with 6.9–10.7 g m⁻² with rice straw application in Inceptisol plots. These findings suggest that although CH₄ emissions from soils of volcanic origin are low, they show proportionate increases with added straw (C) comparable to those from other higher-emitting soils.

Inorganic Fertilization

Reports on the effects of mineral nitrogen fertilizer application (i.e., source, method of application, and amount) on CH₄ production and emission are difficult to interpret and inconsistent. Some form of fertilizer is necessary to ensure adequate plant development, which subsequently increases CH₄ emission through increased plant biomass and root activity. On the other hand, the lack of adequate fertilization could result in poor plant growth and yield as well as premature death, which would increase CH₄ emission through C made available by plant decay. The use of ammonium sulfate fertilizer may reduce CH₄ emission through the competition by sulfate-reducing bacteria for hydrogen or the presence of hydrogen sulfide toxicity.^[1]

Water Management

CH₄ emission rates are highly sensitive to soil aeration controlled through water management. Periodic drainage of irrigated rice paddies, which significantly decreases CH₄ emissions, may be the most effective method of mitigating them. In the Philippines, midseason drainage

of 2 weeks' duration at either mid-tillering or panicle initiation was very successful in suppressing CH₄ flux rates by up to 60%. However, the flux of nitrous oxide, a potent greenhouse gas, increased sharply during the drainage period.^[11] A single midseason drain reduced seasonal CH₄ emission rates by 50% in fields in the United States. In addition, multiple short periods of drainage (2–3 days) approximately every 3 weeks during the growing season reduced CH₄ emissions to an insignificant amount.^[12]

Soils

Rice soils prone to CH₄ production belong mainly to the orders of Entisols, Inceptisols, Alfisols, Vertisols, and Molisols. Oxisols, most of the Ultisols, and some of the Aridisols, Entisols, and Inceptisols are less favorable to CH₄ production when flooded. After the flooding of calcareous or alkaline soils (high pH), CH₄ production may occur almost immediately, whereas emission may take weeks to develop with acid soils and may not occur at all in highly acid soils. In general, sandy soils high in organic C produce more CH₄ than clay soils with similar C content.^[1] A strong positive correlation between seasonal CH₄ emission and % sand has been observed in Vertisols in Texas.^[13] However, CH₄ production may be limited in all soils if water percolation and the resultant oxygen levels are high.

Rice Cultivars

The effect of cultivar differences^[14] contributes to variation in CH₄ emissions from rice fields. A study of five rice cultivars in irrigated fields near Beijing, China, indicated that CH₄ emission during the tillering–flowering stage varied by a factor of two. CH₄ emission from eight different cultivars grown under comparable conditions near New Delhi, India, differed by as much as one order of magnitude. CH₄ emissions from six different cultivars grown in Louisiana fields showed that semidwarf varieties evolved significantly less CH₄ than tall varieties. Similarly, in an Indonesian paddy field, CH₄ emissions from eight popular modern varieties of rice varied, depending on the cultivar, from 32.6 to 41.7 g m⁻² and from 51.3 to 64.6 g m⁻².^[15] Fields planted with the Italian rice cultivar Lido showed CH₄ emissions (24–31%) lower than fields planted with the cultivar Roma.^[16] The difference in CH₄ emissions was attributed to a significantly lower gas transport capacity in the Lido cultivar. A study in Texas of 10 rice cultivars^[14] showed a cultivar-dependent variation in seasonal CH₄ emissions, ranging from 17.95 to 41.0 g m⁻². Cultivars exhibiting higher seasonal CH₄ emissions also exhibited higher soil acetate concentrations,^[17] suggesting that intervarietal differences in CH₄ emissions may be the result of different soil organic substrate levels and, hence, different rates of CH₄ production.

CONCLUSION

Significant progress has been made in understanding the processes of CH₄ flux, their temporal and spatial variations, and their relationship to country level and global atmospheric trace-gas inventories. This progress has come through international and interdisciplinary research collaborations and cooperation. The known factors governing the levels of CH₄ emissions from flooded rice fields, including climate and photosynthetic activity, added organic fertilizers, type of inorganic fertilizers, water management, soil type, and choice of rice cultivar, are largely understood. These factors have been incorporated into effective process-level models capable of calculating site-specific emission strengths throughout the world. Further integration of mechanistic models with geographic information systems of factors controlling emissions can provide improved estimates of the CH₄ source strength of various rice ecologies and farming practices and lead to environmentally and socioeconomically sound management and mitigation policies.

Rice Paddies: Methane Emissions, Mitigating

Kazuyuki Yagi

National Institute for Agro-Environmental Sciences, Tsukuba, Japan

Abstract

The atmospheric concentration of methane (CH_4) is increasing rapidly. Because it is a radiative trace gas and takes part in atmospheric chemistry, the rapid increase could be of significant environmental consequence. Of the wide variety of sources, rice fields are considered as an important source of atmospheric CH_4 , because the harvest area of rice has increased by about 70% during the 20th century and it is likely that CH_4 emission has increased proportionally. Due to the large amount of the global emission from rice cultivation, reduction of CH_4 emission from this source is very important in order to stabilize atmospheric concentration. In addition, because of the possibility of controlling the emission by agronomic practices, rice cultivation must be one of the most hopeful sources for mitigating CH_4 emission.

PROCESSES CONTROLLING CH_4 EMISSIONS FROM RICE FIELDS

Table 1 provides a summary of measured CH_4 emissions at a number of specific research sites around the world.^[1,2] It should be noted that CH_4 fluxes from rice fields show pronounced diel and seasonal variations and vary substantially with different climate, soil properties, agronomic practices, and rice cultivars.

Processes involved in CH_4 emission from rice fields are illustrated in Fig. 1. Like other biogenic sources, CH_4 is produced by the activity of CH_4 producing bacteria, or methanogens, as one of the terminal products in the anaerobic food web in paddy soils. Methanogens are known as strict anaerobes that require highly reducing conditions. After soil is flooded, the redox potential of soil decreases rapidly by sequential biochemical reactions.

Flooded paddy soils have a high potential to produce CH_4 , but part of CH_4 produced is consumed by CH_4 oxidizing bacteria, or methanotrophs. In rice fields, it is possible that a proportion of CH_4 produced in the anaerobic soil layer is oxidized in the aerobic layers, such as the surface soil–water interface and the rhizosphere of rice plants.

The emission pathways of CH_4 that is accumulated in flooded paddy soils are as follows: diffusion into the flood water, loss through ebullition, and transport through the aerenchyma system of rice plants. In the temperate rice fields, more than 90% of CH_4 is emitted through plants,^[5] while significant amounts of CH_4 may evolve by ebullition, in particular during the early part of the season in the tropical rice fields.^[6] Therefore, it is concluded that possible strategies for mitigating CH_4 emission from rice cultivation can be made by controlling either production, oxidation, or transport processes.

OPTIONS FOR MITIGATING CH_4 EMISSION

Water Management

Mid-season drainage (aeration) in flooded rice fields supplies oxygen into soil, resulting in a reduction of CH_4 production and a possible enhancement of CH_4 oxidation in soil.^[7,8] A study using an automated sampling and analyzing system clearly showed that short-term drainage had a strong effect on CH_4 emission, as shown in Fig. 2. Total emission rates of CH_4 during the cultivation period were reduced by 42–45% by short-term drainage practices compared with continuously flooded treatment.^[9] These results indicate that improvement in water management can be one of the most promising mitigation strategies for CH_4 emission from rice fields. Increasing the rate of water percolation in rice fields by installing underground pipe drainage may also have an influence on CH_4 production and emission.

Soil Amendments and Mineral Fertilizers

The progress of soil reduction can be retarded by adding one of several electron acceptors in the sequential soil redox reactions. Sulfate is one of the most promising candidates for this strategy because it is commonly used as a component of mineral fertilizer and soil amendment. Field measurements have shown that CH_4 emission rate decreased at most 55–70% by application of ammonium sulfate or gypsum.^[10,11]

Additions of other oxidants, such as nitrate and iron-containing materials, may influence CH_4 emission from rice fields, as well as adding oxidants, dressing paddy fields with other soils that contain a large amount of free iron and manganese may decrease CH_4 emission. Other chemical candidates are nitrification inhibitors and acetylene releasing materials.

^aThe data are for the fields without organic fertilizer.

Organic Matter Management

In rice cultivation, fresh organic matter and animal wastes are often applied as fertilizers. In the fields, a proportion of the biomass of previous crops and weeds remains in soils at the start of rice cultivation. Such organic matter is decomposed in soils and acts as a substrate for fermentation reactions. Many researchers have demonstrated that incorporation of rice straw and green manure into rice paddy soils dramatically increases CH₄ emission.^[7,10,12] The impact of organic amendments on CH₄ emissions can be described by a dose–response curve which adopts

correction factors for composted and fermented organic matter.^[6] Mitigation of CH₄ emission requires the quantities of organic amendments to be minimized.

Field experiments also indicated that composted or fermented organic matter increased CH₄ emission much less than fresh organic matter due to a lower content of easily decomposable carbon.^[6,7] Therefore, stimulation of composting organic amendments appears to be a promising mitigation option. Plowing the fields during the fallow period and promoting aerobic degradation of organic matter are also likely to reduce CH₄ emission.

Others

Different tillage and cropping practices change the physical, chemical, and microbiological properties of the plow layer soil and may reduce CH₄ emission. These include deep tillage, no tillage, and flooded rice–upland crop rotation.

Selecting and breeding rice cultivars that emit lower CH₄ is a desirable approach because it is easy to adopt. There are four points to consider for selecting cultivars: 1) they should exude low levels carbon from their roots; 2) they should have a low level of CH₄ transport; and a high level of CH₄ oxidation in the rhizosphere; 3) they should have a higher harvest index in order to reduce organic matter input into soil after harvest; and 4) they should be suitable and have a high productivity when other mitigation options are performed.

Fig. 2 Effect of water management on CH_4 emission from a rice paddy field. The arrows indicate the period of midseason drainage in the intermittent irrigation plot and the timing of final drainage in both of the plots.

PROBLEMS AND FEASIBILITY OF THE OPTIONS

If the above mitigation options could be applied to world's rice cultivation, global CH_4 emission from rice fields

could decrease significantly. However, there are several formidable obstacles to adopting the mitigation options into local rice farming. Table 2 summarizes the problems and feasibility of the individual mitigation options along with the efficiency of the options.

Application of some options is limited to specific types of rice fields. In particular, altering water management practices may be limited to rice paddy fields where the irrigation system is well equipped. Long midseason drainage and short flooding may cause possible negative effects on grain yield and soil fertility. Improving percolation by underground pipe drainage requires laborious engineering work. The increased water requirement is another problem in the water management options because water is a scarce commodity in many regions.

Cost and labor are serious obstacles for applying each option to local farmers. Most of the mitigation options will decrease profitability and the farmer net returns in the short run. To overcome these obstacles, an effort to maximize net returns by joining CH_4 mitigation and increased rice production will be needed as well as by political support.

It is recognized that the mitigation options should not have any significant trade-off effects, such as decreased rice yield, a decline in soil fertility, or increased environmental impact by nitrogen compounds. The development of anaerobic conditions in soil by flooding decreases the

Table 2 Evaluation of the mitigation options for CH_4 emission from fields.

Problem for application

decomposition rates of soil organic matter compared with aerobic soils, resulting in soil fertility being sustained for a long time. Flooded rice cultivation shows very little growth retardation by continuous cropping. Some mitigation options may reduce these advantages of rice fields. Application of sulfate-containing fertilizer may cause a reduction in rice yield due to the toxicity of hydrogen sulfide. Mid-season aeration and soil amendments may induce nitrogen transformation resulting in enhanced nitrous oxide emissions.^[16,17]

Rice Paddies: Methanogenesis

Ronald L. Sass

Department of Ecology and Evolutionary Biology, Rice University, Houston, Texas, U.S.A.

Abstract

Irrigated rice cultivation is among the larger global sources of atmospheric methane (CH_4) and will become an even larger source due to increasing food demands. Because it is one of the few sources where the management of CH_4 emission is possible, it is also likely to be a critical focus of mitigation efforts. Several mitigation options include water management, soil amendments, organic matter management, cultivar selection, and field preparation, with water management being the most promising. However, because rice is also the world's most important wetland crop and the primary calorie source of a large fraction of the world's population, mitigation efforts must be based on sound agricultural practices as well as good scientific judgment.

INTRODUCTION

Methane (CH_4) is a radiatively active trace gas with approximately 21 times more infrared sorbing capability per molecule than carbon dioxide as a source of potential global warming.^[1] Worldwide, agricultural sources of CH_4 may account for as much as 40% of the total annual emission of atmospheric CH_4 with a significant portion contributed by rice cultivation. To meet the rice supply of growing populations, rice cultivation will continue to increase at or beyond its existing rate. Based on the projected population growth rates in countries where rice is the main food crop, it is estimated that the world's annual rough rice production must increase from a 1990 value of 473 million tons to 564 million tons by 2000 and 781 million tons by 2020—a 65% increase (1.7% per year). In South Asia, e.g., rice production is projected to double by the year 2020.^[2] Because arable land is limited in major rice-growing areas, increased production has to be achieved mainly by intensifying cropping (i.e., two or three crops per year) and developing new technologies rather than expanding the area of rice cultivation. Irrigated rice will continue to dominate production. Irrigated rice land comprises about half the total harvested area but contributes more than two-thirds of the total grain production. With available agronomic practices, this trend will lead to significantly increased CH_4 emissions.

CH_4 PRODUCTION AND EMISSION FROM RICE FIELDS

The processes involved in CH_4 emission from flooded rice to the atmosphere include CH_4 production in the soil by methanogens, CH_4 oxidation within oxic zones of floodwater and the soil by methanotrophs, and vertical transport from soil to the atmosphere. CH_4 is produced in the terminal step of several anaerobic degradation chains. The

amount of CH_4 produced in flooded rice soils is primarily determined by the availability of methanogenic substrates and the influence of environmental factors. The sources of organic carbon for methanogenic substrates are derived from rice plants via root processes and biomass litter or added organic matter. The environmental factors affecting CH_4 production include soil texture, climate, and agricultural practices, such as water regime and management. Plant-mediated transport is the primary mechanism for the emission of CH_4 from rice paddies, with approximately 90% of CH_4 transported to the atmosphere through the aerenchymal system of the rice plants. The rice aerenchymal system not only transports CH_4 from the rhizosphere to the atmosphere but also promotes the movement of atmospheric oxygen into the rhizosphere supporting CH_4 oxidation. More than 50% of the generated CH_4 is oxidized during the rice-growing season.^[3]

DISTRIBUTION OF CH_4 EMISSIONS FROM RICE AGRICULTURE

Rice is grown under a variety of climatic, soil, and hydrological conditions in over 90 countries of the world and on all continents except Antarctica. The ecosystems within which rice is grown vary widely with respect to elevation, rainfall pattern, depth of flooding and drainage, soil type, and the variety of rice planted. Fields of rice can be found from 50° N in the regions of China and Japan to 40° S in the southern regions of Australia. Rice is grown from sea level to altitudes of more than 2500 m. It is a unique crop since it adapts to a broad range of soil water content. It grows well in flood-prone areas of South and Southeast Asia (as much as 5 m of floodwater) and in drought-prone upland areas of Asia, South America, and Africa.^[4]

A rich variation in local cultural patterns as well as in natural conditions can be found in the various regions of the

world where rice agriculture is practiced. These variations are reflected in different regional and country values of CH_4 emission rates.^[5] Rice agriculture can be conveniently divided into the following four categories based on water availability: upland or dry rice, rainfed lowland rice, flood-prone rice, and irrigated rice. The relative CH_4 flux strength for different rice ecosystems follows the order: irrigated rice $\geq$ favorable rainfed rice $>$ flood-prone rainfed rice $\geq$ deepwater rice $>$ drought-prone rainfed rice $>$ tidal wetland rice. Upland rice is not a source of CH_4 because it is grown in well-aerated soils. Differences in crop residue treatment, types and amounts of organic amendments, scheduled or opportunistic aeration periods, soil classification and texture, fertilization practices, and choice of rice cultivars are major causes for variations in CH_4 fluxes in irrigated rice systems. Table 1 presents the scaling factors for CH_4 emissions with different ecosystem water regimes and organic amendments relative to continuously flooded (irrigated) fields without organic amendments. An estimate for each

of these different systems is obtained by multiplying the expected CH_4 emission from a continuously flooded field without organic amendments by the two relevant scaling factors. The highest CH_4 fluxes are observed in continuously flooded fields receiving organic amendments such as green or animal manure. The lowest CH_4 fluxes are recorded in fields with low residual carbon content, multiple aeration periods, poor soils, low fertilization, poor rice growth, and low grain yields.

The CH_4 source strength of rainfed rice is highly uncertain because of the high variability in all factors controlling CH_4 emission. CH_4 fluxes are generally lower from rainfed rice because of drought periods and low rice yields. The availability and use of recycled soil carbon residues and available organic amendments are also generally less in areas where rainfed rice is grown compared to the areas of irrigated rice. CH_4 fluxes may approach those from irrigated rice in highly flood-prone rainfed areas. Some areas of deepwater rice may exhibit an even higher CH_4 source strength than the irrigated rice because of long flooded growing periods and high rice biomass production, even though grain yields are low. The source strength of tidal wetland rice is small because generally it is affected by salt water high in sulfate.^[5,8]

Table 1 CH_4 emission scaling factors for rice ecosystems relative to continuously flooded fields without organic amendments.

	Scaling factor	Range
Rice ecosystem		
Upland	0	
Irrigated		
Continuously flooded	1.0	
Intermittently flooded, single aeration	0.5	0.2–0.7
Intermittently flooded, multiple aeration	0.2	0.1–0.3
Rain fed		
Flood prone	0.8	0.5–1.0
Drought prone	0.4	0–0.5
Deep water		
Water depth 50–100 cm	0.8	0.6–1.0
Water depth >100 cm	0.6	0.5–0.8
Organic amendments		
Straw, animal manure, green manure, agricultural wastes, etc.:		
0 t ha ⁻¹ (inorganic fertilizer only)	1.0	
1–2 t ha ⁻¹	1.5	1.0–2.0
2–4 t ha ⁻¹	1.8	1.5–2.5
4–8 t ha ⁻¹	2.5	11.5–3.5
8–15 t ha ⁻¹	3.5	2.0–4.5
15+ t ha ⁻¹	4.0	3.0–5.0
Fermented amendments, compost, biogas pit residue, etc.:		
1–6 t ha ⁻¹	1.0	1.0–1.5
6–12 t ha ⁻¹	1.5	1.0–2.0

RANGE OF GLOBALLY OBSERVED SEASONAL EMISSIONS

Observed CH_4 emissions for a single rice-cropping season reported from several countries around the world show large ranges, reflecting local as well as regional differences in agricultural, biological, and climatic factors. An average of all such reported median country CH_4 emission values from irrigated rice is 27.23 g CH_4 m⁻², with a range from a minimum value of less than 1 g CH_4 m⁻² to a maximum value of 155 g CH_4 m⁻².^[5] A data set from five countries (China, India, Indonesia, Thailand, and the Philippines) obtained under a network coordinated by the International Rice Research Institute showed averages of less than 30 g CH_4 m⁻² under mineral fertilization.^[9] Emissions under organic amendments were generally higher than 20 g CH_4 m⁻² except for a site in northern India where average emissions remained as low as 2 g CH_4 m⁻².^[9] In a series of studies in Texas, conducted between 1991 and 1995, 32 seasonal CH_4 emission rates were measured under the conditions of continuous flooding and no organic amendments, in three different soil types with 11 different rice cultivars. These studies show a measured mean CH_4 emission of 21.99 $\pm$ 8.53 g CH_4 m⁻² and a median value of 19.84 g CH_4 m⁻².^[10] The situation is similar for rainfed and deepwater rice. For rainfed rice, the median of average observed value is 13.33 g CH_4 m⁻², and reported ranges are from 1 to 68 g CH_4 m⁻².^[5] Emission values^[11] for rainfed rice range from 8 g CH_4 m⁻² (drought-prone rice) to 16 g CH_4 m⁻² (flood-prone rice). The average CH_4 emission value for

deepwater rice ranges from 12 g CH₄ m⁻² (50–100 cm water depth) to 16 g CH₄ m⁻² (>100 cm water depth).^[5]

Estimates of the global release of CH₄ from rice paddies made range from 12 to 200 Tg yr⁻¹.^[10] Many early estimates are based on a limited number of field measurements and range widely. The Intergovernmental Panel on Climate Change (IPCC) suggested a most probable value of CH₄ emitted from global rice paddies to be 60 ± 40 Tg yr⁻¹.^[12] Three estimates based on extensive field data and model calculations report ranges of 25–54,^[13] 21–41,^[14] and 33–49 Tg yr⁻¹.^[5] Considering these results, a best estimate ranging between 26 and 50 Tg yr⁻¹ for the annual world CH₄ emission from rice fields is posited.^[10] Asia accounts for approximately 90% of the world rice production^[15] and over 90% of the annual CH₄ emissions from rice fields. The following seven Asian countries lead the world in rice production and CH₄ emission: China, India, Indonesia, Thailand, the Philippines, Japan, and the Republic of Korea.^[10]

MITIGATION OF CH₄ EMISSIONS FROM RICE FIELDS

The IPCC^[16] calculated that stabilizing the concentration of atmospheric CH₄ at the 1990 level would require a 15–20% reduction in total CH₄ emission. Irrigated rice cultivation is among the larger global sources of atmospheric CH₄ and will become an even larger source due to increasing food demands. Because it is one of the few sources where the management of CH₄ emission is possible, it is also likely to be a critical focus of mitigation efforts. Several mitigation options to reduce atmospheric CH₄ concentrations have been developed through research efforts.^[2,8,17,18] These include water management, soil amendments, organic matter management, cultivar selection, and field preparation, with water management being the most promising. However, because rice is also the world's most important wetland crop and the primary calorie source of a large fraction of the world's population, mitigation efforts must be based on sound agricultural practices as well as good scientific judgment.

Rice Paddies: Soil Management

Beijing, China

Abstract

As a global staple food, rice (*Oryza sativa* L.) plays an important role in food security. Due to the long-term flooded condition, paddy soils have a series of special physical, chemical, and biological characteristics. Therefore, managing paddy soils is critical to rice production and climate change mitigation. Management strategies of paddy soils should be based on the goals of increasing rice production, enhancing nutrient use efficiency, improving soil quality, and enhancing the economic and environmental benefits.

INTRODUCTION

Rice (*Oryza sativa* L.) is an important food staple of the world. About 166.1 million hectares (Mha) of paddy rice was harvested in the world in 2013.^[1] During the period of 1981–2013, the harvested area of paddy rice increased by 21.1 Mha with average yield increased from 2730.7 to 4547.8 kg ha⁻¹ globally.^[1] Asia is the most important producer and consumer, providing 91.0% of the world's paddy rice grown in 89.4% of world's paddy fields, and the yield increased from 2859.3 to 4486.7 kg ha⁻¹ during 1981–2013.^[1] China is one of the top contributors of paddy rice to the world, and the harvested areas and yield reached 30.2 Mha and 6725.7 kg ha⁻¹ in 2013, respectively.^[1]

Rice is mostly cultivated and managed as paddy soil, which is typically waterlogged and formed through seasonal irrigation. A marked alteration of hydromorphic soil properties induces specific processes of paddy soil formation through redox potential oscillations under long-term paddy rice cultivation.^[2] Such specific properties result in hydric Anthrosols because of the characteristic management of paddy soil.^[3] Therefore, suitable paddy soil management strategies play an important role in rice production and global food security. Moreover, paddy soil is a major source of global methane (CH₄) emissions on 11% of the total agricultural emissions. It is also an important source of nitrous oxide (N₂O).^[4] The formation of paddy soil is related to rice cultivation and is affected by many factors, e.g., terrain hydrological conditions, parent material, climate, and cropping system strategies. Thus, management strategies of paddy fields are vital to maintain rice production and reduce emissions of greenhouse gases (GHGs).

CHARACTERISTICS OF PADDY SOILS

Paddy fields are sited primarily on alluvial soils such as in deltas and flood plains of large rivers, coastal plains, fans, and lower terraces. Thus, paddy soils have many special characteristics that depend on frequently anthropogenic management practices under rice-based cropping systems. Alternate dry–wet cycles and soil tillage play an essential role in profile formation and a series of physical, chemical, and biological properties of paddy soils. Therefore, paddy soils share some special characteristics despite wide differences in parent materials. In addition, soil properties change strongly with increase in soil age.^[2]

Compared to upland soils, the water-holding capacity, soil organic matter (SOM), and microbial biomass carbon are higher under paddy soils. For example, Chen et al.^[5] reported that water-holding capacity, soil organic carbon (SOC), and microbial biomass carbon under paddy soil were 19.0%, 33.7%, and 12.1% higher than that under upland soil at 0–20 cm depth, respectively.^[5] Moreover, the seasonal variations of soil temperatures in paddy soils are more stable with the enhancement of the soil heat capacity through increased water and decreased air in the cultivated layer during the flooding period. Stabilization of soil temperatures benefits both rice growth and yield. Furthermore, changes in soil temperatures within a paddy field are related to the depth of the soil layers, soil saturated moisture regime, infiltration rate, and temperature of the irrigation water.^[6]

Paddy soils are generally comprised of oxidized and reduced zoned in the plow layer.^[7] Under flooding conditions, the oxidized layer is formed at the water–soil interface due to diffusion of aquatic oxygen into the surface soil.

The periodic change of redox reactions is the most obvious biochemical change in paddy soils, the intensity of which is indicated by the redox potential (E_h). The E_h of paddy soils ranges from -200 to -300 mv to $+500$ to $+700$ mv, which also reflects the proportional relationship between dissolved oxide and reduzate (a high E_h indicates more oxides).^[7]

Generally, waterlogging associated with rice cropping enhances accumulation of SOC. The accumulation of SOC in paddy soils may be due to the high input of rice residues combined with slow decomposition under anaerobic conditions. However, mechanisms of SOC accumulation in paddy soils are not well understood. Proposed mechanisms include the relation between SOC accretion and CH_4 emissions and the interactions between SOC and E_h or other environmental factors that will help to understand how the aeration condition and E_h affect the accumulation and stabilization of SOC.^[8–10]

The transformation of substances in paddy soils is a special biochemical process that occurs under long-term flooding conditions. The form of inorganic nitrogen exists as ammonium more than nitrate (NO_3^-) in paddy soils due to the reduction of NO_3^- by denitrification and leaching in the subsurface layer.^[7] Moreover, some noxious substances are formed due to incomplete decomposition of SOM under conduction of low oxidation reduction potential.^[2,7,8]

MANAGEMENT APPROACHES

Recommended management practices of paddy soils are based on the goals of increasing crop yield, enhancing nutrient use efficiency, ameliorating soil quality, and increasing economic and environmental benefits. On the contrary, the characteristics of paddy soils are also vital factors that affect the management strategies. Prior studies and farming experiences indicate that farming practices (e.g., rational tillage, water management, residue management, and fertilization) are conducive to maintaining paddy rice productivity, enhancing food security, mitigating global climate change, and sustaining the paddy system.

Tillage Practices

Tillage practices have been one of the most important factors that change the soil environment directly. For most paddy fields, plow tillage as a conventional practice has a long history on a global scale. In conventional tillage, a plow pan can develop at the 20–30 cm depth following an extended period of plowing, which can slow the transmission of water and nutrients across this layer. The plow pan can also reduce the leaching of nutrients in the rice paddy, even with long-term flooding.^[11] Moreover, the disruption of substance transmission through the plow pan can

decrease redox potential, reduce toxic materials, regulate organic matter accumulation by affecting the distribution of elements (i.e., iron), and maintain the nutrient supply.^[8,9] On the contrary, tillage practices also affect the formation and function of paddy soils, especially changing properties (i.e., soil bulk density, enzymatic activity, and microbial activity) in the plow layers.^[12] No-till (NT) farming (or direct seeding) in paddy soils has been gradually adopted in China, Pakistan, Bangladesh, India, and elsewhere, due to rising labor prices and short term around period for sowing the next crop (e.g., wheat). However, with the long duration of NT, the plow pan may gradually disappear and increase the water infiltration rate, thus increasing the risk of nutrient leaching. Thus, rational tillage systems in paddy soils need to be further studied for improving the nutrient use efficiency in rice-based systems.

Irrigation

In general, paddy cultivation consumes large quantities of water to meet the evaporative demand during the entire rice-growing season. Thus, the adoption of water-saving irrigation practices has a critical role in sustainable rice production due to the decreasing water availability and competing user of water. Meanwhile, water management is recognized as one of the most important practices associated with CH_4 and N_2O emissions from paddy fields. Traditional continuous flooding in paddy fields increases CH_4 emissions, even though it reduces N_2O emissions. Further, mid-season aeration and alternate dry–wet cycles have been widely adopted to save agricultural water and increase rice yield. However, there is a trade-off between CH_4 and N_2O emissions from paddy fields with mid-season aeration and dry–wet cycles.^[13] The adoption of controlled irrigation can effectively mitigate the integrative greenhouse effect produced by CH_4 and N_2O emissions from paddy fields while also ensuring high rice yield.^[13] Additional research is needed to quantify the integrative greenhouse effect under other major water-saving irrigation practices (e.g., intermittent irrigation, flooding–mid-season drainage–frequent waterlogging with intermittent irrigation, and flooding–mid-season drainage–reflooding–moist intermittent irrigation).

Residue Management

Large amounts of rice residues are produced in the rice-growing countries. Traditionally, large proportion of rice residues has been burned after rice harvest, causing loss of nutrients and SOM, as well as air pollution. The adoption of appropriate residue management practices can have a strong effect on soil physical, chemical, and biological properties, which can improve soil fertility, enhance SOC sequestration, and reduce GHG emissions.^[14]

Innovative technologies have greatly enhanced paddy rice production. Conservation agriculture, including

rational tillage systems, residue mulching, and crop rotation, has gained popularity on a global scale and has contributed to sustainable productivity of paddy soils through improved crop yield, enhanced SOC sequestration, and mitigation of GHG emissions.^[11,13] Other management strategies such as fertilization (new fertilizer type and methods), pesticides, and irrigation are conducive to improve the use efficiency of materials and inputs to enhance paddy rice production and reduce the GHG emissions.^[11,15] Integrated management systems are an efficient strategy to achieve the goals of sustaining food supply, mitigate climate change, and improve agroecosystem sustainability in paddy soils. High yield amelioration of paddy soils requires the incorporation of rational tillage, fertilization (with farmyard manure), and water management (aeration and reflooding).

CONCLUSION

Paddy rice production is critical to global food security. Thus, managing paddy soils is vital to both food security and mitigating global climate change. Therefore, a deep understanding of the formation process and characteristics of paddy soils is helpful to select the suitable managements for rice production. Adopting a holistic approach in the management of soil and water resources (including rational tillage systems and integrated nutrient and pest management practices) in paddy soils is important for decreasing water and soil losses, improving efficiency, enhancing rice production, reducing GHG emissions, and sequestering SOC.

Rocks

Vsevolod V. Dobrovolsky

Moscow State Pedagogical University, Moscow, Russia

Abstract

Soil develops, as a rule, on a mineral substrate that plays the role of soil skeleton and accumulates plant residues and products of their biochemical transformation. The significance of soil-forming mineral substrate (parent rock) is very high, since it constitutes about 95% of the total mass of most soils. Soil inherits all peculiarities of mineral substrate connected with the particle size distribution, mineralogical and bulk chemical composition, and many physico-chemical properties important for the agronomic technology. Fully developed soil with the regular sequence of certain horizons determined by climatic factors can be formed only on those mineral substrates that are loose and porous enough to provide the free migration of water, air, mezofauna, and easy penetration by plant roots. These are the properties of late-tertiary and quaternary loose substrates covering nearly all the terrestrial surface. The loose consistency is also characteristic of the volcanic eruptions, on which specific soils—Andosols—are formed.

INTRODUCTION

Consolidated rocks play a less significant role in pedogenesis because their high density is unfavorable for an active interaction between biota, water, gases, and mineral matter. Soils formed on these rocks consist, as a rule, of a single horizon of plant residues decomposed into different degrees with an admixture of fine eolian material. These soils can also include a shallow transitional horizon consisting of rock debris, loose allochthonous material, and illuvial humus. The composition of hard rocks can strongly affect the possibility of full-profile soils' development and the trend of pedogenesis. On dense quartzites in case of moderate climate, the regolith cannot be formed even for $n = 10^4$ yr. However, on clayey-calcareous rocks (marls) the soils with the complete sequence of soil horizons can be formed in a much shorter time. The high content of calcite in hard rocks and consequent neutralization of acid products of organic matter decomposition results in the occurrence of soils with a mollic horizon, even in the case of humid climate and forest vegetation. At the same time, extremely high content of some chemical elements in parent material [e.g., magnesium (Mg) in serpentinites] may lead to low bioproductivity of ecosystems and, consequently, to weak development of pedogenic features.^[1]

With respect to loose substrates, although mantle deposits differ by the mechanisms of transport and accumulation (glacial, fluvial, eolian, etc.), all of them consist of weakly consolidated products of rock weathering. The earth's crust is composed mostly of compact crystalline rocks consisting of minerals of the silicate class. Being exposed on the surface, these rocks undergo mechanical disintegration, as the crystalline and chemical structures

of minerals formed at a great depth become unstable. For this reason, a very slow but continuous processes of total decomposition (hydrolysis) and transformation into new mineral structures occur.^[2] Therein lies the essence of rock weathering (hypergenesis).

COARSE AND FINE MINERAL MATERIAL OF MANTLE DEPOSITS INHERITED BY SOILS

The mineral components of mantle deposits can be subdivided into three groups.^[3] The first one includes the coarse particles of prevailing bedrock minerals, i.e., quartz and silicates. The stability of these minerals is different and decreases along the following range: quartz (the most stable), feldspar, mica, amphibole, pyroxene, plagioclase, olivine.^[4] For this reason, redeposited products of weathering are characterized by the prevalence of quartz, lower contents of feldspars and micas, rare amphiboles, single plagioclases and pyroxenes, and very infrequent olivine.

Some of the minerals contained in widespread rocks in very small quantities are very stable. These are ilmenite, magnetite, garnet, epidote, zircon, rutile, disthene, staurolite, etc. They are insignificantly changed during the redeposition of weathering products and can be easily separated because of a considerable specific weight (2.9) as a single fraction of coarse particles (the so-called "heavy fraction"). Despite the mineralogical heterogeneity, this fraction cannot cause a significant variation in the bulk chemical composition of mantle deposits, since it usually constitutes less than 1% of their total mass. However, the composition of heavy fraction points to the original location of weathering products. Since microelements

specific for certain territories are concentrated in this fraction, its study allows us to define the mineralogical–geochemical provinces of mantle deposits, the peculiarities of which are inherited by soils.

The second group of mineral components of mantle loams comprises minerals formed as a result of hypergene transformation of structures of primary silicates. Secondary (hypergene) silicates have a specific (layered) structure and are represented by very fine particles (<0.002 mm) that can be observed only with the use of electron microscope and with magnifications of several thousands.^[5]

The structure of hypergene silicates and their large specific surface account for the ability of these minerals to adsorb cations (which can be equivalently substituted by other cations) from solution. Hypergene silicates are represented by the group of clay minerals: kaolinite, halloysite, montmorillonite, hydrochlorides, hydromicas, etc. They differ by the cation exchange capacity, which is the lowest for kaolinite and the highest (about 10 times higher) for montmorillonite.

Soils formed on mantle deposits inherit the content and composition of clay minerals. The cation exchange capacity of many soils is related to the mineralogical composition of mantle deposits being prevalent parent rocks.

The composition of clay minerals may predetermine not only soil characteristics but also microrelief. For example, in the case of tropical and subtropical climates, with alternations of dry and humid seasons on heavy substrates with montmorillonite predominance, Vertisols with well-pronounced microrelief gilgai are developed.^[6]

Another important property of mantle deposits is also connected with fine-earth minerals. This is the color of deposits inherited by soils. In loamy and clayey substrates, clay particles serve as chromophores (coloring agents), because F(III) hydroxides are firmly adsorbed (non-exchangeable) on their surface. These iron (Fe) hydroxides are neither destroyed during erosion and redeposition nor are dissolved in acids and alkalis and can be removed only in reduction conditions, as trivalent iron is reduced to an easily soluble bivalent iron. The latter is used for determining Fe(III) hydroxides in soils.^[7]

There are several modifications of iron oxides formed in different reduction–oxidation, acid–alkali, and temperature conditions. In mantle deposits beyond tropical areas, Fe(III) hydroxides (amorphous α -FeO*OH) on the surface of clay particles have yellow–brown colors: from 7.5 to 10YR according to the Munsell's Color Charts.^[8] In the tropics and partly in the subtropics, such iron substances are represented mainly by α -Fe₂O₃, and several modifications of FeO*OH and have bright red and orange colors (from 10R to 2.5YR), which could be changed only in upper horizons (Fig. 1).

The color of parent rock is well preserved in conditions of a free gas exchange between soil and atmosphere.

Fig. 1 Podzolized (bleached) soils on red-colored substrate.

Therefore, many tropical soils have red or orange colors, and soils of cold and temperate regions have yellow–brown colors. In conditions of hindered gas exchange (caused by overmoistening of loose deposits) and oxygen deficiency, parent rocks and soils acquire bleached bluish-gray color (from 5GY to 5BG) due to iron reduction and dissolution (Fig. 2).

In case of pedogenesis on light-colored limestones, the color of deep soil horizons is inherited from the rock, whereas the upper horizons turned black because of humus accumulation (Fig. 3).

CHEMICAL COMPOSITION AND PARTICLE SIZE DISTRIBUTION IN MANTLE DEPOSITS

The bulk chemical composition of mantle deposits and their soils depend on the proportion of fine and coarse mineral fractions. A high content of silicon (Si) results from the predominance of quartz; the contents of aluminum (Al), Fe, potassium (K), and Mg depend on the amount of clay minerals (fraction <0.002 mm). The average chemical composition of mantle deposits and soils differs from that of the earth's crust by an

Fig. 2 Gleyed soils with bluish-gray color due to iron reduction.

increased share of Si, decreased shares of Al, calcium (Ca), Mg, K, and sodium (Na), and by the prevalence of Fe(III) over Fe(II).

The particle size distribution is the content of different particle size fractions in parent rocks and soils expressed in percent. This is a very important characteristic of parent rocks, because it results in mechanical and hydrophysical properties (stickiness, swelling capacity, rupture resistance, porosity, permeability, water capacity, water availability for plants, etc.) of soils formed on these deposits.

The particle size distribution in mantle deposits varies considerably. It is connected with the chemical composition of mantle deposits and their soils: The higher the share of clay fraction, the lower is the Si content, and the higher are the contents of Al, Fe, Mg, and K.

THE TRANSFORMATION OF MANTLE DEPOSITS

The third group of mineral components of mantle loams includes epigenetic mineral neoformations appearing after the accumulation of loose deposits as a result of soil-hypergenic processes. These are concretions and

Fig. 3 Mollisol on limestone—inheritance of white color in deep soil horizons and black color of upper humus horizon.

cements of Fe(III) and Mn(IV) hydroxides; calcareous concretions, pore encrustation, and films on fissure walls; Ca, Mg, and Na sulfates and Na chlorides in the form of efflorescence, individual crystals, and druses. Some epigenetic minerals are formed not by free crystallization in voids and fissures, but as a result of the selective metasomatic substitution of certain elements, which mainly affects very fine clay particles, while coarse mineral grains are only weakly corroded.^[9] The phenomenon of hypergenic metasomatism is most typical for the oxides of Fe(III) and Mn(IV) and, to some extent, for calcium carbonate. Besides the neoformation of individual minerals, epigenetic processes play an important role in forming the micromorphological fabric, porosity, and bulk density of mantle deposits. Deposits with most common particle size distribution (silty loams) have a bulk density of 1.5 g/cm³ and a porosity varying from 40% to 50% of the total volume.

From the aforesaid it follows that mantle deposits, the most widespread soil-forming substrates, are one of the most important factors of pedogenesis responsible for the particle size distribution, chemical composition, physico-mechanical, hydrophysical, and physico-chemical properties of many soils.

Root Growth: Pressure at the Soil—Root Interface

Rabi K. Misra

Faculty of Science, University of the Sunshine Coast, Sunshine Coast, Queensland, Australia

Abstract

In order to avoid reduction in root and plant growth in soils of high strength, soil and crop management options need careful consideration. Permanent, long-term reduction of strength in soils of unfavorable structure is difficult even with tillage. Sustainable soil and crop management practices incorporating minimum traffic and high retention of organic matter through residue management hold the greatest promise for favorable root growth and crop production by maintaining the soil strength below critical levels.

INTRODUCTION

Plant roots apply force to make cylindrical cavities in soil, which allow them to grow and elongate. However, in certain situations, roots need to apply only a small amount of force, for instance, when a root tip reaches an existing channel (made by earthworms, roots of a previous crop, or cracks from shrinkage of soil). Studies in homogeneous soils of uniform strength usually show development of localized zones of compressed soil around roots.^[1]

A root growing in soil exerts force within the zone of elongation behind the root cap (Fig. 1) until the elongation zone reaches maturity and the force shifts to a new elongation zone developed through cell division. Roots apply force in axial and radial directions.^[2] As roots have a cylindrical shape (some departure from cylindrical shape is expected for roots in very strong soils), they apply force over a cylindrical area. Therefore, root growth pressure is an estimated quantity from separate measurements of force and area. For axial pressure, area over which the force is exerted is circular, which can be estimated from the measurement of diameter in the elongation zone of the root. For radial pressure, force is exerted over a cylindrical surface, so both diameter and length of the root are important. At the soil–root interface, axial and radial root growth forces are expected to vary with time, and so does the area over which these forces are exerted.

THEORETICAL BASIS

The estimation of root growth pressure from direct measurements of force and diameter of root is time-consuming, and these measurements are possible for single roots of seedlings in a laboratory. To overcome this, many studies rely on assessing soil resistance to root growth (equivalent to indirect estimation of root growth pressure) from rapid measurements of soil strength using penetrometers. Penetrometers measure pressure required to push root-shaped

(conical) metal probes into soil. These pressures are referred to as penetrometer resistances or cone indices in the literature. There is often a good correspondence between root growth pressure and penetrometer pressure^[3]

when roots are not growing in cracks or holes. However, penetrometers tend to overestimate root growth pressure by 1.8 to 7.5 times.^[3,4] Critical values of penetrometer resistance, which halves root elongation rates in soil, are shown in Table 1. Data in this table show substantial differences in root growth response between crops, which gives the opportunity to select crops tolerant to soils of high strength.

The nature of soil deformation by root tips and cones and the mechanical stress at the soil–root and soil–cone interfaces can be explained well using the theory of soil mechanics for homogeneous soils and aggregate.^[1,3,11,12]

These and similar theories and associated experimental evidence suggest that friction at the soil–root interface could be substantially lower than the friction at the soil–cone interface. Studies suggest that cells produced from sloughing of root cap might reduce soil–root friction, which would allow roots to penetrate strong soils without the need to exert as high a pressure as a penetrometer cone.^[13]

Despite the differences between penetrometer resistance and root growth pressure, cone penetrometers continue to be used as a surrogate measure of root growth pressure at the soil–root interface and in the diagnosis of soil compaction to determine the extent of soil limitation to root growth in the field.

ROOT GROWTH PRESSURE IN COMPACTED SOILS

In compacted soils of high bulk density and high soil strength, root growth rate is reduced because the axial pressure applied by roots is not sufficient to overcome soil strength, and root growth may stop when root is unable to deform soil. In this situation, axial root growth pressure is expected to reach a maximum. In less compacted soil,

Fig. 1 Developmental zones in a seedling root of cotton.

axial force applied by roots increases with time until the pressure is sufficient to overcome soil strength and then it declines. Values of maximum axial growth pressure are well documented, and they are in the range of 0.2–1.5 MPa (Table 2). However, direct estimates of radial root growth force and pressure are scarce in the literature. The importance of radial root growth pressure for root penetration in compacted soils is also not so well understood as the axial root growth pressure.

MEASUREMENTS OF AXIAL ROOT GROWTH PRESSURE

In the late 19th century, Pfeffer reported maximum axial and radial growth pressures for primary roots of a limited number of seedlings.^[14] Although Pfeffer's measurement technique is now refined, the principle of measurement has changed little.

Most reports on root growth force are limited to primary roots of young seedlings (≤ 1 -week old) in laboratory experiments. Measurements on roots of older seedlings (e.g., nursery-raised tree seedlings) and comparison of forces exerted by lateral roots with primary roots suggest that the ability of roots to apply force may decline with age

^aMeasured on lateral root of nursery seedlings.

and possibly with increased branching order.^[18] This might be one of the reasons for the development of herringbone rooting pattern at the highest branching order observed for many species of plants.

Axial root growth force is commonly measured on intact seedlings with a 20–40 mm long primary root. The root axis is anchored to the bottom of a pot, allowing 3–5 mm of the root tip to protrude through a hole at the bottom of the pot. This pot is filled with soil or vermiculite (containing adequate water and nutrients) with care to avoid any damage to the root. The protruding root tip is then pushed into a hole in the soil in a second pot to an extent that a narrow air gap of ~ 0.5 mm between the two pots is maintained (Fig. 2). A force-measuring device supports the second pot. Axial force is commonly measured using a data logger over short time intervals (5–10 minutes) until it reaches maximum and then declines (Fig. 3). Measurements are usually stopped when the maximum axial force is known. Root diameter is measured in the air gap following the termination of the experiment, and these data are used to calculate the circular area over which maximum axial force would have been exerted. Maximum axial growth pressure is calculated as maximum force divided by the area. In many experiments, a wet, porous ceramic block with a cylindrical hole

Fig. 2 Experimental arrangement for the measurement of axial root growth force exerted by a typical seedling at the soil–root interface.

Fig. 3 Typical variation of axial root growth force with time for seedling roots of pea.

Source: From Misra.^[18]

(to position the root tip) replaces the second pot containing the soil. These experiments aim to measure maximum axial root growth pressure to establish the ability of seedling root to exert axial force.

CONCLUSION

Data on maximum root growth force are generally consistent between various experimental methods and laboratories. However, there are some uncertainties with root diameter measurements. Most measurements of root diameter are made in the air gap after removal of the seedling from the apparatus. This might overestimate the root diameter, as roots can expand slightly when the mechanical stress is removed.^[18] Root growth pressure in soil may also be influenced by variables other than soil strength such as root temperature, species of plants, and cultivar.

Roots must perform work to grow through soil. Energy requirement for root penetration is expected to be high in strong soils. As energy for root growth is derived through assimilates fixed by leaves, growth and partitioning of resources might be affected in plants growing on strong soils.

In order to avoid reduction in root and plant growth in soils of high strength, soil and crop management options need careful consideration. In situations where the zone of high soil strength is close to the surface, loosening of surface soil with shallow tillage (using discs, tines, and ploughs) will reduce soil strength. Tillage with deep ripping is recommended where high strength occurs in the subsoil. However, care is needed to avoid excessive tillage that is known to deteriorate soil structure, decrease organic matter, and accelerate erosion. Permanent, long-term reduction of strength in soils of unfavorable structure is difficult even with tillage. Sustainable soil and crop management practices incorporating minimum traffic and high retention of organic matter through residue management hold the

greatest premise for favorable root growth and crop production by maintaining soil strength below critical levels.

Institute of Water Saving Agriculture in Arid Areas of China, Northwest A&F University, Yangling, China

Abstract

Plant root monitoring systems directly observe the growth status of plant roots in Plexiglas soil columns without damaging the plant, providing real-time and dynamic data of plant root formation, transpiration, and root growth throughout the day. The small retractable windows on the Plexiglas soil columns are used to monitor and sample the rhizosphere soil for moisture, nutrients, temperature, and microbiological indicators, allowing for the analysis of various physiological and biochemical indicators. The plant root monitoring system can also be used for root pruning experiments, which can reduce errors caused by single-field experiments and thus providing a way to conduct intensive study of plant roots functions. The system is easily maintained, widely used, and operates effectively.

INTRODUCTION

Plant roots are one of the most important components of plants, and its growth status is closely related to the growth of the whole plant. Roots absorb, transfer, and store nutrients and water, as well as function of fixing and supporting plant body,^[1] playing an important role in the biogeochemical cycle of ecosystems.

While the root systems have been focused in biological research, due to the complexity and difficulty of observing and sampling, its progress has been relatively slow. As it is relatively difficult to directly observe the growth status of root systems, physiological and biochemical research of root systems is not intensive enough. The primary method for analyzing root systems rely on methods that are destructive and result in incomplete sampling, such as digging,^[2] soil-coring,^[3] and profiling methods.^[4] These methods are time consuming and labor intensive, terminate the growth of plants, and additionally, the collected samples are incomplete or have different degrees of damage, making the results difficult to interpret. The commonly used method for *in situ* root system observation is by installing an observation device in the soil, such as the rhizobox method^[5] and the minirhizotron technique.^[6,7] The minirhizotron method is one of the most commonly used methods when monitoring the growth of root systems in the fields. The ray computed tomography (CT) method is the most commonly used method for monitoring root system morphology, and it

utilizes the mature ray imaging principle to generate images of the root system in soil samples, such as the X-ray CT^[8,9] or magnetic resonance imaging,^[10] however, this method requires relatively expensive equipment and it can only observe limited space, thus the application is not universal. The selection of research method for plant roots influences the results with respect to aboveground part of plant. Therefore, it is necessary to develop methods that allow for *in situ* observation of root growth and spatial distribution of root morphology. In order to better study plant root, it is of great significance to establish specialized research devices that allow automatic monitoring, analysis, and condition control of plant root system.

ROOT EXCAVATION METHOD

Analyzing the root system architecture and physiology and biochemistry of the roots could be realized through excavation of the root system close to the ground (Fig. 1). The method employed a sampling device to excavate the plant root system and its surrounding soil within certain scopes,^[2] in approximately 10 cm intervals. After washing through soil sieves with aperture size over 0.25 mm, and using scanned images of the root system within the sampling range, this method allows for quantitative observation of branched roots length at different levels and number of branches. It also allows measuring of relevant

Fig. 1 Excavation method.

physiological and biochemical indicators of the root system. The excavation method is less labor intensive, more cost effective, and less time consuming, but its shortcoming is that the sampling range is limited.

ROOT-CORING METHOD

Root auger with inner diameter over 6.0 cm is used to conduct stratified sampling of the plant root system (Fig. 2). Under field conditions, multipoint sampling is generally carried out along rows and vertical rows, and the sampling is usually conducted in 10 or 20 cm

Fig. 2 Root-coring method.

intervals. The soil sieve with bore diameter over 0.25 mm is used to wash the composite samples of roots and soil, and the morphological analysis of the root system within the sampling range and the measurement of physiological and biochemical indicators could be conducted through image scanning. The longitudinal sampling range of this method is not limited, but it requires high labor intensity.

MINIRHIZOTRON METHOD

The minirhizotron method installs minirhizotrons (transparent Plexiglas tubes with length of 1.8 m and external diameter of 5.2 cm) in field experiments.^[11,12] Before installation of the minirhizotrons, the bottom of the tube is sealed and then launched with a 45° angle to the ground, then exposed part above ground (about 30 cm) is covered with black tape after fixing the minirhizotrons. A rubber cap is installed on the tube nozzle in case water or dust falls into the tubes. The distance between the installed minirhizotrons is generally 50 cm and each group of four minirhizotrons is used to collect data from the same treatment. The minirhizotrons are adopted to conduct dynamic monitoring, and the system collects images from $1.05 \times 1.45 \text{ cm}^2$ range by connecting a microcamera with slide control to the computer using image scanning software for observation. After the images of the root systems are collected, the root analysis software WinRhizoTron is used for analysis to acquire root parameters such as root length, root diameter, number of root tips, and surface area. However, images acquired via minirhizotron method can have complicated soil background and poor root continuity (Fig. 3).

Fig. 3 Minirhizotrons technique.

Fig. 4 MRI of plant roots.

NUCLEAR MAGNETIC RESONANCE METHOD

Multislice spiral CT can observe the microscopic structure in human bodies, thus the multislice spiral CT machines can also be used to conduct scanning and 3-D imaging of plant root system. It allows for the collection of root system volume using a CT3D workstation, and then the image postprocessing software MIP can be used to generate images. The quality of images is influenced by the scanning technical solutions (parameters), imaging technical solutions (images processing and algorithm reconstruction), and density difference between plant root system and growth medium. The method is subject to the limitation of root growth environment; therefore, it is very difficult to obtain complete data of *in situ* root morphology, especially at the middle to late stage of crop growth (Fig. 4).^[13]

ROOT-OBSERVING SYSTEM

The observing system built with steel and concrete based on the plant root system, with an observing chamber (standard holes) in which 20 Plexiglas columns with height of 2.8 m can be placed (Fig. 5).

The aboveground part is designed according to the requirements of plant root system and adopts the arched architecture made of rustproof steel. It is composed of a roof made of sheet material that shields light and blocks rain, the surrounding parts made of waterproof material that enables ventilation, and the mobile greenhouse supplies power and water, with a steel lifting device and aboveground antiradiation plate (Fig. 6).

The roof of the underground part of the system is constructed by pouring steel and concrete according to the system requirements. In addition, the standard concrete holes for placing Plexiglas soil columns are reserved. It consists of Plexiglas soil columns for observing and

Fig. 5 Plexiglas soil columns for root observing.

monitoring (which is developed separately and contains 14 minirhizotron windows and lifting infrastructure), automatic monitoring system of evaporation mass balance, automatic monitoring system of soil column moisture, temperature monitoring, soil-shading equipment and lifting support, illumination system required for observation, and power supply system for electric equipment such as experiment instruments (Fig. 7).

Fig. 6 Aboveground part of root observing system.

Fig. 7 Underground part of root observing system.

Auxiliary facilities of the system include devices that allow for automatic monitoring, analyzing, and researching system of plant root system. These include SM200-DT80 soil moisture dynamic monitoring system (soil moisture transducer and digital collector), root analysis system WinRHIZO, precise electronic balance (placed in the bottom of soil columns and its measurement range is within 600 kg and the sensitivity is ± 50 g), monitoring and analyzing instruments such as plant root pruning trepans. In addition, according to the system requirements, there is a tank to wash the roots in the sedimentation tank.

Root growth status can be observed directly without doing damage to original plants using the root system automatic monitoring system (Fig. 8). The plant root monitoring subsystem allows for real-time and dynamic collection of data, along with images of the root system, and measurement of plant transpiration and growth parameters throughout the day using the auxiliary facilities. The plant root and leaf analyzing subsystem can be used to analyze images of plant root system and leaves and explore the relationship between leaf growth and root growth. Soil moisture, nutrients, temperature, and microbiological indicators can be monitored using the small retractable windows. The retractable windows can also be used to prune the roots to collect samples or carry out analyses on physiological and biochemical indicators, improving the reliability of root physiological and biochemical experiments and provide favorable conditions for intensive study of plant root system. This system can be used for a long period and is fast, intuitive, time saving, easy operation, fast measurement, and high working efficiency when compared to the traditional root sampling methods. By employing the

Fig. 8 Observation of *in situ* root system.

plant root research system, it is convenient to conduct a variety of analyses including the root physiology and biochemistry in the cultivation of crops, forage grass and flowers, as well as spatial distribution of root system morphology and ecological research of plant root system. Studies of crop growth and water-saving irrigation in agricultural ecosystem, physiological and biological responses of plant root system to adversity stress, such as salt, drought, and heavy metals, and senescence of plant root pruning are some of the examples that this method could be employed effectively.

Abstract

Salt-affected soils decrease crop productivity at local and global scales. The extent of soil salt problems is likely to increase if no measures are taken to limit soil salinization and sodication. Management and reclamation of salt-affected soils require a combination of agronomic practices, including hydraulic, mechanical, amending, and cropping practices. The selection of proper management practices is relative to the soil, water, crop, and human available resources.

INTRODUCTION

Salt-affected soils can be defined as soils on which the growth of most crop plants is limited by an excess of easily soluble salts. Salts are considered easily soluble when they are more soluble in water than gypsum. Salts may include chlorides, sulfates, carbonates, and bicarbonates of sodium, potassium, magnesium, and calcium. The salt concentration in the soil solution is usually measured by the electrical conductivity (EC) of the soil saturation extract. A soil is saline if the EC of the extract is higher than 4 dS m^{-1} .^[1] However, plant growth may be severely affected or inhibited at much lower levels of EC. Limiting EC values change with the ionic composition of the soil solution and with the plant species and variety grown. Sodic soils are salt-affected at $\text{EC} < 4 \text{ dS m}^{-1}$ (Table 1). In sodic soils, the high sodium content relative to other cations is the main factor affecting plant growth. The amount of sodium is usually expressed as exchangeable sodium percentage (ESP) or sodium adsorption ratio (SAR). The critical level of ESP for growth reduction depends on many interacting factors and may vary from <6% to >15%. There is a continuum of plant responses to the continuous increase of salt stress with increasing salt or sodium concentrations in the soil. Saline and sodic conditions, although very different, are often implicated in adversely affecting plant performance, so that terms such as salinity, saline, and salinization are generically referred to soil conditions and processes leading to salt and sodium stresses on plants.^[2]

EXTENT AND DISTRIBUTION

Salt-affected soils are most common in arid climates with evapotranspiration greater than precipitation for at least part of the year (aridic, ustic, or xeric soil moisture regimes), but they are present at any latitude and altitude. Salinization by improper irrigation management was a major cause of degradation of the Nile Delta, the Mesopotamian Plain, and the valley of the Yangtze and the Hwang Ho.^[3] Estimates of the extent of soil salinity and sodicity problems vary from 5% to 10% of the world land area. Estimates from the Food and Agriculture Organization, Land and Water Development (FAO-AGL)^[4] indicate that >800 million hectares are salt-affected, i.e., >6% of the world land area (Fig. 1). Salinization affects about 70 million hectares of irrigated lands, about one-third of the world irrigated area. The *World Map of the Status of Human-Induced Soil Degradation* indicates that about 77 million hectares are affected by human-induced salinization,^[5] comprising 45 million hectares of irrigated and 32 million hectares of rain-fed agricultural land.^[4] Salinity problems also affect greenhouse crops, mine spoils, and disposal areas. Part of the yield loss occurs on irrigated lands, which are otherwise highly productive. In the irrigation district of Ciudad Juarez Valley in Mexico, the productivity of 70% of the lands is hindered by salinity. On average, 25% of irrigated Mexican lands are salt-affected. The impact of yield losses is magnified at a local scale because salt-affected soils are not uniformly distributed, threatening the economic welfare of some regions and countries. In Bangladesh, 24% of the total land area is salt-affected with a rapid expansion

Table 1 General classification of salt-affected soils.

Soil class	EC (dS m ⁻¹)	SAR	ESP (%)
Non-saline non-sodic	<4	<13	<15
Saline	>4	<13	<15
Saline-sodic	>4	>13	>15
Sodic	<4	>13	>15

during the last-quarter of the 20th century from <1 million hectares to >3 million hectares. In Australia, almost 20% of the land is salt-affected.^[4]

Salt-affected soils not used for crop production (e.g., salt flats) are a potential source of salts for the salinization of surrounding fields. According to Oldeman et al.,^[5] the annual rate of loss of agricultural land by salinization, alkalization, and waterlogging is about 1.5 million hectares. Previous estimates reported 10 million hectares of agricultural land loss per year.^[6] The rate of increase is likely to vary widely across regions and from year to year, but all data suggest an increasing extent of salt-affected lands, especially where the natural resources are scarce and the growing human population increases pressure on soils. Changes in the global environment are likely to increase yield losses consequent to soil salinity. The predicted increase of the sea level from thermal expansion of sea water ranges from 15 cm to >50 cm by the year 2100.^[7] The rise of sea water is likely to worsen salinity problems from the tidal inundation of coastal lands. On the other hand, there is no evidence to suggest that elevated atmospheric carbon dioxide (CO₂) would increase the level of salinity suitable for plant growth.^[8] Increased CO₂ is expected to increase plant growth only on non-saline soils, magnifying yield losses due to soil salinity.

CROP TOLERANCE

Soil salinity and sodicity limit the potential area of growth of sensitive crops. All plants are sensitive to salts at some concentration, but the limiting concentration varies with plant species and variety. Crop tolerance is defined in relation to the level of salinity causing yield losses. High salt concentration may lead to plant death and no yield. Decreased growth occurs above a soil critical salt or sodium concentration (tolerance threshold). Crop yield reductions in salt-affected soils result from the alteration of various metabolic processes in plants under salt stress. Negative effects of excess of salts in the soil solution include increased osmotic pressure limiting water uptake (physiological drought), abnormal pH and ionic competition limiting nutrient uptake, and ionic toxicity. Total salinity effects always depend on the specific soil ionic composition. The negative response of plants to low water potential may prevail in saline soils, while single ion toxicity or nutritional imbalance may be particularly severe in sodic soils. Soil structural impedance of plant growth is common in the absence of sufficient Ca²⁺. Structural problems derive from crusting, formation of compacted layers, poor infiltration, and poor permeability to water and air. In waterlogged soils, anaerobic conditions may enhance salinity stresses.

In all plants growing on saline media, a part of the metabolic energy is diverted to ion transport, synthesis of organic osmolytes (contributing to osmotic adjustment to low water potential), and ion compartmentation preventing ion toxicity.^[2] Osmotic adjustments in salt-tolerant plants need to follow seasonal changes in soil salinity and water availability. In general, plants that are more salt-tolerant tend to grow more slowly at low

Fig. 1 The distribution of salt-affected soils. The percentage of salt-affected soils on the total land surface is reported for each region of the world.
Source: From FAO-AGL.^[4]

salinity levels than less-tolerant plants. Broadly adaptable plants can produce good yields where strong temporal changes of soil salinity occur in the soil. But such plants, tolerant to a wide range of salinities, perform less well at any salinity than less adaptable plants at their optimal salinity.^[8] Reduced yield in tolerant plants can be related to: 1) greater allocation of organic carbon (C) in the roots of tolerant plants at the expense of leaf area; 2) decreased use of the solar radiation; and 3) low transpiration rate. Soil salinity interacts with climate and other edaphic factors in determining yield. Reduced availability of water in the soil is concomitant to higher evaporative demand in the leaves. The adaptation to soil salinity is a reduction in the capacity for photosynthetic C assimilation consequent to the necessity of minimizing evapotranspiration. In general, crops are less sensitive to salinity in glasshouse conditions than outdoors. At low soil fertility levels, plants may appear more tolerant to salinity than at high fertility levels if salinity is not the limiting factor of yield. On the other hand, nutrient deficiencies induced by salinity and sodicity can further reduce low yields due to low fertility.

In natural conditions, soil salinity varies with depth and time. Plants extract water from the least saline parts of the soil surrounding the roots. Plants may be able to tolerate high salinity levels in the root zone if occurring only for short periods of time during the growing season. Soil salinity may peak at different stages of the crop, when plants may be more or less sensitive. Consequently, the critical point for yield reductions varies with the duration of salt stress and stage of development. Growth can be inhibited at any stage of the biological cycle. Severe reductions of yields can be due to low germination and limited early plant establishment. Yield reductions can be caused by reduced vegetative growth and/or by perturbation of the reproductive phases. Developmental shifts of relative salt-tolerance are common during plant life and vary with cultivar and environment. Often, qualitative yield reductions enhance total yield losses.

A common classification of crop salinity tolerance distinguishes five categories (Table 2). Sodium is not considered a limiting factor in the above classification.

Table 2 The classification of crop salt-tolerance based on the values of EC above which yield loss begins.

Relative tolerance	Critical EC (dS m ⁻¹)	Examples of crops
Sensitive	<1.3	Beans
Moderately sensitive	1.3–3.0	Rice, corn
Moderately tolerant	3.0–6.0	Wheat
Tolerant	6.0–10.0	Barley, cotton
Unsuitable	>10.0	Most crops

Source: From Ayers & Wescot.^[9]

Table 3 The classification of crop exchangeable sodium tolerance.

Relative tolerance	ESP (%)	Examples of crops
Sensitive	<15	Beans, corn
Semitolerant	15–40	Rice, wheat
Tolerant	>40	Barley, cotton

Note: Growth is usually already affected at lower values of ESP, and crop production is usually excluded at ESP >30.

Source: From Ayers & Wescot.^[9]

A classification of sodium tolerance of crops consists of three groups (Table 3). Sodium-tolerance tables are usually based on nutritional responses in absence of soil structural degradation, which generally excludes crop production at ESP >30.^[9] These classifications are based on the agronomic criterion of comparing the relative yield of each crop on saline media to its yield on normal non-saline media. Published tolerance tables provide a reference of relative salt tolerance of crops under irrigation without local climatic specifications. Such data refer to the duration of salinity from late seedling stage to maturation with irrigation, fertilization, and pest control maintained optimal for each crop species and variety at the time of the experiment. Tolerance tables may apply to individual cultivars in the absence of interactions between soil salinity and other environmental factors.

CONCLUSION

Salt-affected soils decrease crop productivity at local and global scales. The extent of soil salt problems is likely to increase if no measures are taken to limit soil salinization and sodication. Management and reclamation of salt-affected soils require a combination of agronomic practices, including hydraulic, mechanical, amending, and cropping practices.^[4] The selection of proper management practices is relative to the soil, water, crop, and human available resources.

Improved crop salt tolerance can contribute to the remediation of soil salt problems because it:

1. Extends the choice of crops that can grow at each soil salinity level.
2. Allows irrigation using more saline water.
3. Increases soil organic matter and improves soil structure.

Consequently, tolerant crops may assist establishing a proper water balance and reduce the need and cost of reclamation measures such as leaching.

Information on crop response to salinity and sodicity needs to be updated in relation to changes of plant materials, agronomic practices, and climatic conditions. A range of values in the continuum of salt and sodium stresses would

be better suited than a single critical value to represent the tolerance or sensitivity of a plant since the intensity of salt stress depends on many other factors determining yields.

Salt-Affected Soils: Nitrous Oxide Emissions

G.S. Dheri

Babu S. Brar

Debankur Sanyal

Department of Soil Science, Punjab Agricultural University, Ludhiana, India

Abstract

Nitrous oxide (N_2O) not only is an important greenhouse gas but can also contribute to the depletion of the stratospheric ozone layer. Agricultural sectors are emitting a large quantity of N_2O as nitrogen fertilizers are widely applied. However, a few studies have been conducted on N_2O emissions from salt-affected soils compared to not salt-affected soils. Possible reasons of variation in N_2O emissions are mainly due to differences in soil microbial activities caused by the presence of salt or manuring with certain organic amendments. More studies are needed to elucidate mechanisms of N_2O emissions from salt-affected soils.

INTRODUCTION

Nitrous oxide (N_2O) is the third most potent greenhouse gas (GHG), contributing 6% share (0.17 W m^{-2}) of total radiative forcing caused by well-mixed GHGs.^[1] It is also the most significant anthropogenic ozone-depleting compound.^[2] The mean global mole fractions of N_2O in 2013 reached 325.1 ± 0.1 ppb with an annual increase of 0.80 ppb for the decade ending in 2013.

Agricultural soils are the single largest contributor of the global N_2O emissions.^[3] In agricultural soils, N_2O emissions mainly originate from mineral nitrogen (N) applied with fertilizers and manures, mineralization of soil organic N including crop residues, and biologically fixed N.^[4] There is strong need to identify sources and sinks of N_2O .

Salt-affected soils contain excessive concentrations of soluble salts, exchangeable sodium, or both.^[5] Nearly 6–10% of earth's land area and 77 million hectares of irrigated land area are salt-affected.^[6] Saline and sodic water are used by farmers due to lack of better quality irrigation water in the arid and semiarid regions of the world. Continuous irrigation of soil with saline and saline-sodic water deteriorates soil physicochemical properties and adversely affects yields of different crops.^[7]

Emissions of N_2O from salt-affected soils are a well-reported phenomenon but not clearly well explained or documented. In this entry, we discuss the mechanisms of N_2O production in salt-affected soils and how it differs from the mechanisms in not salt-affected soils (i.e., normal soils).

SOIL EMISSIONS OF N_2O

Microbial processes of nitrification and denitrification are responsible for the production of N_2O in soils.

The underlying mechanism behind the production of N_2O is the depletion of oxygen (O_2), subsequent anaerobic conditions, and reduction of oxidized forms of N to their reduced forms as nitrate (NO_3^-) in denitrification process. NO_3^- is utilized as terminal electron acceptor by facultative and obligate anaerobic bacteria.^[8]

The principal regulatory mechanism of denitrification is fluctuation of partial pressure of molecular oxygen.^[9] The concentration of NO_3^- (or NO_2^-) in the soil is another important regulator, and the third important factor is the amount of available organic carbon (C).^[10] Soil water content is the main factor that controls O_2 diffusion in soil and, thus, nitrification and denitrification. Small changes in soil water content can have a significant effect on N_2O emission.^[11] Soils having high clay content are more prone to denitrification as those easily get waterlogged, causing anaerobic conditions.^[12]

HOW MECHANISMS OF N_2O PRODUCTION IN SALT-AFFECTED SOILS DIFFER FROM THOSE IN NOT SALT-AFFECTED SOILS

Nitrification and denitrification processes coexist within the same soil aggregate due to microsite variability.^[13] N_2O produced in soil is a by-product of the oxidation of NH_4^+ to NO_2^- and NO_2^- to NO_3^- during nitrification under aerobic conditions. Production of N_2O is also possible in denitrification during the reduction of NO_3^- to N_2O under anaerobic conditions or the oxidation of NH_4^+ to NO_2^- and NO_2^- to NO_3^- with a subsequent reduction to N_2O (nitrifier denitrification).^[14] During nitrification, N_2O is produced by two pathways: nitrifier denitrification, i.e., $\text{NH}_3 \rightarrow \text{NH}_2\text{OH} \rightarrow \text{NO}_2^- \rightarrow \text{N}_2\text{O} \rightarrow \text{N}_2$, and hydroxylamine oxidation, i.e., $\text{NH}_3 \rightarrow \text{NH}_2\text{OH} \rightarrow \text{NO} \rightarrow \text{N}_2\text{O}$.^[14] Thus,

under optimum moisture conditions because of high-rate NO_3^- transformation, production of N_2O remains high until all NO_3^- and NO_2^- are eliminated.

Soil salinity slows down N mineralization and accumulation of NO_3^- , thereby influencing the enzymatic activities responsible for denitrification and N_2O emissions.^[15] The high $\text{N}_2:\text{N}_2\text{O}$ ratios in moderately saline conditions having electrical conductivity (EC) of 12.5 dS m^{-1} and low $\text{N}_2:\text{N}_2\text{O}$ ratios in strongly saline conditions (EC of 56 dS m^{-1}) suggest that under highly saline soils a decline in N_2O reductase enzyme activity enhances N_2O emissions.^[16] The potential of denitrification rate in the saline wetland systems is primarily regulated by organic C, NO_3^- and activity of denitrifying bacteria, exchangeable Na^+ percentage (ESP), and the denitrification rate decreases with a rise in the ESP. Microorganisms in artificially created salt-affected soils, however, have limited time of adjustment to the adverse conditions, and their response to salts might be different from those of microorganisms living for an extended time in soils with high amounts of salts.^[16] The activity of NO_3^- reductase produced by ammonia-oxidizing bacteria (AOB) under anaerobic or limited O_2 conditions during nitrifier denitrification can denitrify NO_2^- to nitric oxide and subsequently to N_2O or N_2 . For example, the AOB *Nitrosomonas europaea* reduces NO_2^- produced during nitrification to N_2O using hydrogen or organic compounds as electron donors; thus, incomplete nitrification results in the release of N_2O .^[17]

The exhaustion of NO_3^- can be in excess to its reduction to NO_2^- -N, N_2O -N plus N_2 under anaerobic conditions. The inhibition of N_2O reductase and/or de novo synthesis may be the possible reason for higher N_2O -N emissions and N_2O -to- N_2 ratio in Texcoco-B (EC = 56 dS m^{-1}) as compared to that in Texcoco-A (EC = 12.6 dS m^{-1}).^[16] Increase in EC from 0.5 to 2.0 dS m^{-1} increased production of N_2O from $3.37 \text{ mg N}_2\text{O-N m}^{-2}$ to $34.30 \text{ mg N}_2\text{O-N m}^{-2}$ that may be due to variation in adaptation of microbial communities to high salt concentrations and ion toxicities.^[18] Another study^[19] discovered that N_2O emissions by *Bacillus subtilis* sp. 2 proceed until the content of sodium chloride (NaCl) in analytically pure culture is lower than or equal to 7%, whereas N_2O consumption occurs only when the content of NaCl is lower than 3%. Such differences in N_2O emission and consumption indicate the higher sensitivity of N_2O reductase to salts than NO_3^- reductase. The nature of salts has profound effects on the production of N_2O in soils incubated under anaerobic conditions. The cumulative production of N_2O in soil treated with different salts-enriched water was in the order of normal water < calcium chloride water < NaCl water (Fig. 1) that indicates that nature of salts influences the sensitivity of reductase and hence production of N_2O .^[20] The N_2O reductase is inhibited by acidic pH and low O_2 concentration, indicating that large salt concentrations will act in the same way.^[16]

Fig. 1 Production of N_2O ($\text{g ha}^{-1} \text{ d}^{-1}$) in soil treated with CaCl_2 - and NaCl -enriched water during a 31-day incubation period under anaerobic conditions.

Source: From Dheri, Lal, et al.^[20] ©2016.

Ding^[21] observed effects of organic amendments such as manure, composts, and plant residues on the rates of N loss through denitrification from soils compared to unamended or mineral N-treated soils. The deleterious effect of high salts concentration on crops can be minimized by incorporating organic material^[22] and by applying gypsum, farmyard manure (FYM), or both under sodic and only FYM under saline-sodic water irrigation.^[23,24] The most probable cause of enhanced N_2O production in manured soil is the increased organic C availability. However, application of organic amendments and soil salinization can increase N_2O emissions.^[25]

CONCLUSION

Emission of N_2O is enhanced from some salt-affected soils, but there are no consistent reports to this effect. Thus, well-designed studies are needed to understand the underlying mechanism(s) of N_2O emission from salt-affected soils. Applications of some commonly used organic or inorganic amendments can enhance. Thus, choice of appropriate soil amendments is also essential to reducing N_2O emissions.

Satellite Mapping

Bruce E. Frazier

Department of Crop and Soil Sciences, Washington State University, Pullman, Washington, U.S.A.

Abstract

Land-observing satellites have provided data about soil that were beneficial to the making of soil maps. In some cases, these data gave information about soil properties, like color, which was used to infer erosion or drainage status. In other cases, the evidence was about landform boundaries, vegetative indicators, or less well-understood spectral patterns expressed in terms of principal components that can be related to soil patterns. These data proved useful to map levels of soil organic carbon, iron oxide, and moisture relationships in plants. Satellites provide flexibility in dates of imagery, wavelength, resolution, and synoptic details, allowing much focused views of land areas to be surveyed.

INTRODUCTION

Soil is that “ecstatic skin of the earth,”^[1] containing much life, which is formed as a 3-D skin over the face of earth. The whole soil is seen only by probing, digging, or otherwise cutting into it to expose its 3rd dimension. For over a century, we have organized the soil’s properties according to classification schemes and mapped its geographic distribution. Only for the last years has there been an opportunity to view the surface of the soil from a satellite. From such a perspective, we must infer the properties that soil has in 3-D by convergence of several forms of evidence. Direct evidence of soil properties is derived by their spectral nature and patterns of distribution. Indirect evidence derives from geomorphology, differences in types of vegetation growing on the soils, differences in vegetation caused by soil properties acting as a source of stress to the plants, and land cover created by man in accordance with soil properties. The indirect evidence is related to three of the state factors of soil formation,^[2] namely: organisms, topography, and parent material.

For collecting direct evidence of soil properties with an optical space-borne sensor, the soil should be bare. The exception may be microwave sensing (not optical), which has shown some success in mapping soil moisture. Low-frequency microwaves partially penetrate vegetation and the soil surface, in addition to clouds, and can be used without light.^[3] Timing is critical for optical sensing except in those deserts where the soil is always bare. Some agricultural soils are exposed to a view from above at planting time, but with the adoption of cropping systems built around no-till and minimum till practices, many agricultural soils are no longer bare at any time. As a result, indirect evidence of soil properties is crucial for mapping by satellite or any other optical airborne sensor. This entry

first describe the available sensors, then research into direct evidence of soil properties, and finally the indirect evidence and applications as described in the literature and then the author’s experience.

AVAILABLE SENSORS

The number of sensors, wavelengths, resolution, and satellites are wide as we enter the new millennium. Private satellites are available that can provide a range of resolutions in the optical wavelengths from high (1 m) to low (1 km) and a range of wavelengths from visible (400–700 nm) and reflective infrared (700–2500 nm) to thermal infrared (8000–14,000 nm). Panchromatic (black and white) imagery that is similar to aerial photography is available from IKONOS,^[4] or QuickBird,^[5] if necessary. Acquisition of images can be timed to capture the ground scene when soils are bare or when soil response patterns are detectable in vegetation. Of course, no one has control over cloud cover; so for persistently cloudy areas, any clear image may dictate the choice of date, and all other factors become secondary.

A wealth of choices of satellite data inevitably leads to the realization that if one is planning to use satellite data to map soils, needs of the survey must be well defined. Are high-resolution data necessary? One-meter panchromatic data may be useful where highly detailed surveys are conducted, but a synoptic view of a wide region will not be available. Would normal color or color infrared imagery show patterns of vegetation that relate to soil properties? These data are available in resolutions from 5 m to 1 km, providing some choices in detail and synoptic views. Is information about water absorption patterns of the landscape important? These data are available from the 30-m

Landsat thematic mapper (TM) sensor that has two bands in the middle infrared region (1550–1750 and 2080–2350 nm). The future will witness more satellites launched by both government and private entities that will provide more choices of wavelength and resolution as dictated by economic feasibility.

DIRECT EVIDENCE

Direct evidence of soil properties in satellite data has been investigated and reported by several authors. Soil organic carbon (SOC), iron oxide, and water are constituents of soil that absorb energy. As long as the soil is bare and dry, information about constituents that appear at the surface can be collected by the satellite. This technique is especially adaptable to areas of the world that employ periods of bare fallow in multiyear cropping systems. Bowers and Hanks,^[6] Condit,^[7] Stoner et al.,^[8] and Baumgardner et al.^[9] provide examples of basic research on energy and soil property interactions that were necessary to understand the wavelengths that are important for satellite sensors and then to understand how to apply the satellite-acquired data. Taking into consideration these basic energy absorption features, Weismiller et al.^[10,11] were able to incorporate detailed soil patterns derived from Landsat multispectral scanner (MSS) data into the survey of Jasper County, Indiana. Spectral map overlays were used in the field with aerial photographs to help locate the hand-drawn boundaries. Spectral patterns were correlated with soil drainage classes. A few years later, Frazier and Cheng^[12] investigated Landsat TM bands and found that ratios of several of the bands could be used to reliably map soil patterns in eastern Washington State. They used bands centered at 483 (TM1), 60 (TM3), 825 (TM4), and 1650 nm (TM5). The ratios TM 1:4, 3:4, 5:4, and 5:3 scaled to 8-bit range formed images that were related to SOC levels and to eroded soils. TM 5:4 pixel values were well correlated ($R^2 = 0.98$) to SOC (g/kg) in samples gathered from the test fields. Likewise, TM 5:3 pixel values were well correlated ($R^2 = 0.96$) with the ratio of amorphous iron to SOC from the field samples. This meant that eroded soils could easily be mapped because elevated amorphous iron/SOC occurred where B-horizons were exposed. Both of these sensors, MSS at 80 m resolution and TM at 30 m resolution, provided data of sufficient quality to benefit soil surveys published at 1:15,840 scale.

INDIRECT EVIDENCE

Indirect evidence of soil properties derived from processing satellite images has been added to actual soil surveys in numerous instances since the Landsat series of satellites was first launched in 1972. Usually, Landsat provides a background image to be used in a reconnaissance survey in an area where little ancillary data are available. Most examples described in the literature were spectral maps

made from individual MSS bands or combinations of bands that covered the visible and near infrared spectra. Soil landscapes observed on images made from Landsat digital data were found to exhibit a characteristic surface geometry, type and density of vegetation, and hydrologic pattern.^[13] Frequent satellite overpasses were seen as an advantage over conventional aerial photography because comparison of multirate images would show soil-specific vegetation changes. Multirate capability also allowed surveyors to acquire low sun elevation images showing detailed hydrologic patterns.^[13]

Roudabush et al.,^[14] in surveys on Arizona rangeland, processed two dates of Landsat imagery. The resulting image consisted of clusters representing soil, landform, or geomorphic features. The clusters were related to soil map unit data within broad landform/parent material units. Upon completion of the survey it was concluded that Landsat spectral data added to the mapping of soils on about 35% of the mapping units.

In Washington State, a general soil map was produced with the intent of illustrating the wide diversity of soils in the state. In Washington, 10 of the 12 soil orders that occur worldwide have been identified.^[15] Normally, a general soil map is made by condensing the detailed map units to achieve an appropriate level of abstraction. In some cases, as in the state of Washington, large blocks of land devoted to wilderness and parks had never been surveyed, and thus, had no prior map units to generalize from. For these areas, a schematic soil map was made using corroborating evidence from geology, climate, landforms, and vegetation. Patterns observed in Landsat MSS data served to define prominent geomorphic boundaries and vegetative indicators that could be incorporated into logical map units.^[16] The contribution of satellite data to the mapping process is shown in Fig. 1 of southeastern Washington, showing glacial outburst flood channels cutting through the Loess-covered Columbia Plateau.^[17] Soils within the channels are formed in less than a meter of Loess over flood gravels and bedrock. Soils outside the channels are formed in deep Loess. Flood channel boundaries are seen because of plant cover differences between the two landforms. Deep Loess soils are cropped to small grains, while shallow soils of the channels primarily support range grasses. The image underlying the general soil map polygons is a mid-February Landsat TM band 5 scene that captures the bright return of middle infrared energy from the dry range grasses in contrast with the dark return from green winter grain crops and bare, moist soils. A few apparent mismatches between the satellite image patterns and soil boundary line locations are evident upon close examination. These occur where irrigation has made cropping within the channels possible, where light toned residue from the fall grain crop is still on the field, and where mapping of channel width was exaggerated to preserve their continuity at a publication scale of 1/750,000.

Wilson^[18] developed and implemented premapping techniques using rectified Landsat 7 multispectral imagery

Fig. 1 Selected polygons from the Washington State general soil map superimposed on Landsat 7 TM band 5 (1550–1750 nm) scene, February 16, 2000. Light-toned X units are shallow soils of the channeled scablands. Dark-toned L units are deep soils of the Loess uplands.

at 30 m resolution for an area of previously unmapped desert in Arizona. He found color band combinations of (5, 4, 2) (5,4, 1) and band ratios of (5/7) (5/4) and (3/1) provided patterns that could be related to the geomorphic units.

What is common to all these examples of satellite contributions to soil mapping is that the data provided information to delineate soil boundaries by traditional standard map production procedures, i.e., lines drawn on photographic base, USGS quadrangle sheets, or mylar overlays. There are also examples of soil modeling,^[19] wherein satellite data are one of the several mapped databases that are used by a model to predict the occurrence of certain soils in wilderness areas. The entire map, a result of a GIS modeling process, is a computer-drawn product based on elevation data, geology maps, vegetation (from Landsat TM data), and climate data or models. Soil map units were classified at the subgroup level of soil taxonomy^[20] and designed to be consistent with requirements of a fourth-order survey.^[21] Landsat TM data were used to map vegetation classes, some of which include indicator species for certain soil properties, and to separate thin soils from bare rock and snow that occur in high elevation alpine areas. Verification was done by transecting the wilderness via existing trails and sampling soils within predicted soil groupings and landscape positions.

CONCLUSION

During the past years, land-observing satellites have provided data about soil that were beneficial to the making of

soil maps. In some cases, these data gave information about soil properties, like color, that was used to infer erosion or drainage status. In other cases, the evidence was about landform boundaries, vegetative indicators, or less well-understood spectral patterns expressed in terms of principal components that can be related to soil patterns. The launch of Landsat IV with the TM instrument brought the first wide-area access to the middle infrared bands. These data proved useful to map the levels of SOC, iron oxide, and moisture relationships in plants. Satellites provide flexibility in dates of imagery, wavelength, resolution, and synoptic details, allowing very focused views of land areas to be surveyed.

Abstract

Soil volume within a given measurement scale can be thought of as composed from soil volumes corresponding to smaller measurement scales. Averaging volumetric soil moisture content across the smaller volumes results in a correct value for volumetric moisture content for the larger scale. Similar averaging soil hydraulic properties, such as moisture retention and hydraulic conductivity, across small scales may not result in the correct values for the larger scale. The reason is that the larger scale represents levels of heterogeneity in soil structure that is absent in small-scale volumes. For the same reason, the spatial variability of soil moisture and soil hydraulic properties appears to be dependent on scale. Scaling as a noun means a relationship between soil moisture data at different scales, whereas scaling as a gerund means relating data at different scales. Upscaling (downscaling) refers to estimating soil moisture or soil hydraulic properties at a scale that is coarser (finer) than the one at which data are available.

INTRODUCTION

Soil moisture and soil hydraulic properties are measured over temporal and spatial measurement scales that are often different from the scales at which knowledge is required. For example, the measurement scale of the moisture release characteristic is equal to the volume of the core, whereas soil surface moisture measured from a satellite has the measurement scale equal to the pixel size of the imagery. Soil water balance calculations are based on subdividing soil into cells, the size of which defines the model scale. Both measurement and model scales define supports, i.e., minimum lengths, areas, volumes, or time intervals below which variation in properties is ignored.

PHYSICS-BASED SCALING

Models of soil structure used for scaling assume the preservation of some structure-related properties across a range of measurement scales or among samples of the same measurement scale.

Similitude-Based Scaling

The similitude model postulates that pore-size distributions in several soil samples of the same size can be converted into each other by simple multiplication of radii by a

sample-specific constant or by adding a sample-specific constant to the logarithms of pore radii as shown in Fig. 1. The Washburn's equation is often used to replace values of pore radii R with values of the maximum matric potential Ψ at which a pore is filled during the drainage, h is the absolute value of matric potential Ψ , and a is the capillary constant

$$h = |\Psi| = \frac{a}{R} \quad (1)$$

Using Eq. 1, one can transform similarity in pore-size distributions into similarity in dependencies of h on saturation degree S as shown in Fig. 1. Therefore, water retention curves of samples exhibiting the similitude should coincide in a “lg h vs. S ” coordinate system if appropriately moved along the axis lg h . Let the expression $h = f_i(S)$ be water retention curves in n samples, $i = 1, 2, 3, \dots, n$. The coincidence of these curves following the shifts will be achieved if, for the same values of h ,

$$\begin{aligned} \lg \lambda_1 + \lg f_1(S) &= \lg \lambda_2 + \lg f_2(S) = \dots \\ &= \lg \lambda_n + \lg f_n(S) = \lg f^*(S) \end{aligned} \quad (2)$$

or

$$\lambda_1 f_1(S) = \lambda_2 f_2(S) = \dots = \lambda_n f_n(S) = f^*(S) \quad (3)$$

where λ_i is the sample-specific scaling constant for the sample “ i ,” $f^*(S)$ is the reference water retention curve, lg

Fig. 1 Similarity of pore-size distributions under the similitude hypothesis; (A) is the distribution of pore volume expressed as saturated degree, and (B) is pore radii transformed into absolute values of matric potentials. Arrows show shifts of the middle reference curve to transform it into other curves.

λ_i is the shift along the axis $\lg h$ needed for the coalescence of the i^{th} curve with the reference curve. The scaling allows the compression of variations in functions $f_i(S)$ into variations in single number λ_i .^[1] The application of this scaling is shown in Fig. 2. Although no ideal similitude is

observed, a significant decrease in variability is achieved by applying scaling, i.e., shifting original water retention curves as shown in Fig. 2. No large different groups of water retention curves are present, and the distribution of values of λ_i is close to the lognormal distribution (Fig. 2).

Fig. 2 Testing the similitude hypothesis with 120 of sandy siliceous, mesic Psammentic Hapludult across $170 \times 210 \text{ m}^2$ area; (A) is the variability of original water retention data; (B) is water retention curves shifted to be close to the reference water retention curves shown as a solid line with an equation; (C) is two examples of shifts of water retention curves; original and shifted curves are shown with filled and hollow symbols, respectively; and (D) is the probability distribution of scaling constant; symbols—experimental data, and line is the theoretical lognormal distribution.

The similitude assumption can be combined with the hypothesis that the Kozeny–Carman law for the hydraulic conductivity K is applicable in soil. Then a coalescence of dependencies $K(h)$ can be achieved.

Scale Invariance of Water Transport Equations

Soil water transport equations can be transformed into dimensionless forms that relate the dimensionless combination of the original dependent and independent variables. Dimensional or inspectional analysis is used for that purpose.^[2] Scaling invariance of the Richards' water transport equation requires, in general, water retention and hydraulic conductivity to be log-linear functions of volumetric water content as follows

$$\lg h = \lg h_0 - b_h \lg \theta \quad (4)$$

$$\lg K = \lg K_s + b_k \lg \theta \quad (5)$$

where the saturated hydraulic conductivity K_s and the air-entry pressure h_0 can be spatially variable, whereas slopes b_k and b_h are the same across the spatial extent of the sampling. Where this scaling invariance applies, the volumetric water content at the depth, z , at the time, t , can be obtained from the volumetric water content, θ' , at another depth z' and at time t' as follows

$$\frac{\theta}{\theta'} = \left(\frac{z}{z'}\right)^{-1/b_h}; \quad \frac{t}{t'} = \left(\frac{z}{z'}\right)^{(b_k+b_h-1)/b_h} \quad (6)$$

Simplified models of water transport, such as the Green–Ampt infiltration model, the unit gradient drainage model, or the model with a negligible gravity, also yield scaling relationships that compress spatiotemporal variations in

water content profiles into spatial variability of one or two dimensionless parameters. To use the same hydraulic properties at different scales, it was suggested to incorporate the scaling directly into water transport equations by using fractional derivatives.

Fractal Scaling Using Self-Similarity, Self-Affinity, and Multiscaling Hypotheses

Self-similarity models are based on the assumption of fractal geometry. Natural objects often have similar features when viewed at different scales. Measures of these features, e.g., the total number of features, the total lengths, the average roughness, and the total surface area, are dependent on the measurement scale. Fractal geometry assumes that this dependence is the same over a range of scales, i.e., scale invariant within this range. Many soil properties were shown to obey fractal scaling.^[3]

To apply fractal geometry, one must have in mind a model of formation of the fractal features in soil. The Sierpinski carpet and the Menger sponge (Fig. 3) are examples of such models that are often used to simulate soil pore space structure. These and other fractal models are obtained by an iterative extraction of similar pieces of progressively small sizes from an initially solid geometrical figure, square in case of the Sierpinski carpet, and cube in case of the Menger sponge. Fractal objects can be also generated from aggregation processes.

Fractal modeling of pore volume based on the Sierpinski carpet and Menger sponge led to the widely used Brooks–Corey equation of soil water retention. The Sierpinski carpet model has been successfully used to develop equations for saturated hydraulic conductivity of macropores in soil.^[4] A fractal model of pore outlines

Fig. 3 The iterative construction of fractal objects; top is the first three stages of constructing fractal surface using the Sierpinski carpet model, and bottom is the first two stages of constructing fractal volume using the Menger sponge model.

has been useful in relating the unsaturated hydraulic conductivity k to soil water retention and the tortuosity caused by fractal surface of pores. Soils with water retention curves from fractal models satisfy the requirement 4 for scaling invariance of Richards' equation and also exhibit the similitude-based scaling 2 provided that the spatial variability of the fractal dimension is not substantial.^[5]

The self-affinity model appears to be appropriate to simulate the spatial variability of soil moisture for large resolutions and extents.^[6] A self-affine surface remains statistically similar to itself when the resolution in horizontal plane increases μ times and the resolution in vertical direction increases μ^H times. The variances of self-affine elevations, z_1 and z_2 , measured at two resolutions, d_1 and d_2 , obey the following scaling relationship: $\text{Variance}(z_1) = (d_1/d_2)^{2H} \text{Variance}(z_2)$. Assuming spatial dependencies of soil moisture contents to be self-affine, one can apply the self-affinity model as shown in Fig. 4.

It has been proposed that multiscaling, or multifractal, models expand the range of resolutions in which fractal scaling is applicable to soil moisture fields. Unlike the generation of Sierpinski carpet or Menger

sponge fractals in which the similarity of structure persists across iterative steps, multifractals are generated by cascade processes that create more heterogeneity as the resolution decreases.

EMPIRICAL SCALING

Physics-based scaling is usually applicable within a range of scales covering one or two orders of magnitude. At larger scales, soil heterogeneity manifests itself by the appearance of new types of heterogeneity, and self-similar scaling ceases to be applicable. A further increase in the scale may reveal new scaling. Empirical observations are usually substituted to proceed from one level of physics-based scaling to another.

Transition from Laboratory to Plot Scale

Transition from the laboratory soil sample scale of 5–10 cm to the plot scale of 1–5 m reveals a change in soil water retention. A regression equation has been developed to convert volumetric water content from the sample resolution to the plot resolution at the same soil matric potential $\theta_{\text{Plot}} = 1.287\theta_{\text{Lab}} - 0.977 \theta_{\text{Lab}}^2$. Saturated hydraulic conductivity measured in soil cores increases according to the power law $K_{\text{sat}} \propto R^m$, where R is the core radius, $m = 0.3 - 0.4$ ($0.6 - 0.7$) for coarse-textured (fine-textured) soils without macropores.

Using Pedotransfer Functions and Soil-Landscape Relationships

The use of pedotransfer functions, i.e., relationships between soil properties, is a common way to estimate effective soil hydraulic properties for large areas with data available from soil survey maps. Because the soil textural and other classes used in soil mapping are quite broad, nonlinear hydrologic models may give distorted answers if average class values are entered in pedotransfer functions. Soil-landscape relationships can be used to describe the variability within soil map units. In particular, the spatial variations of soil hydraulic properties within extents of 10–1000 m correlate with terrain attributes.^[7]

Inverse Modeling

Inverse modeling has been used to estimate effective soil hydraulic properties for large-area supports by matching measured and predicted soil surface moisture, runoff, or infiltration. Simulation studies show a good correspondence between weighted-average hydraulic parameters for individual soil units within the support and parameters found from the inverse modeling.

Fig. 4 Fractal scaling of the variance of soil surface moisture measured with passive microwave radiometry across Little Washita Watershed in Oklahoma in 1992 and 1997 during the drying periods. Observation dates are shown with different symbols, and measurement scale is the pixel size.

CONCLUSION

Scaling relationships both enhance the understanding of soil moisture dynamics and underlying processes and serve as a unique contrivance to overcome the mismatch of scales between measurements available in soil moisture studies, hydrological models, and the applications of soil moisture parameters and values in environmental decision making. One should expect scaling of soil moisture to play a major role in the fast-growing field of data assimilation, i.e., combining data obtained at different scales for environmental monitoring and prediction.

Sediment: Influence on Aquatic Life

Suzanne M. Gray

*School of Environment and Natural Resources, Ohio State University,
Columbus, Ohio, U.S.A.*

Abstract

Soil sediments enter aquatic systems through natural processes such as erosion, run-off, and resuspension and provide necessary components for aquatic ecosystem functioning. However, sedimentary inputs to aquatic systems have increased drastically in the 20th century due to human activities in and around water. This increased sediment load is expected to influence aquatic biota in multifaceted ways while in suspension and through sedimentation. Here, a broad overview of how aquatic life is influenced by increased sediment loads was given, highlighting the general trends of organismal and population-level responses to sediment levels that exceed natural or historical levels. Overall, increased sediment loads caused by human activities are associated with negative responses, such as reduced primary productivity due to the shading effects of suspended particles and a decrease in the depth of the photic zone, and population declines of macroinvertebrates and fish associated with a suite of physicochemical changes to aquatic systems and concomitant changes in the ecological structure of those systems. While extensive research has investigated the influence of increased sediment loads on aquatic biota, linking organismal-level responses to population- and community-level responses, and further to global scale impacts remains a challenge to the field.

INTRODUCTION

The movement of sediments into aquatic ecosystems is a natural process with many beneficial and essential results that contribute to the global sediment flux.^[1,2] However, global rates of sediment inputs to aquatic systems have increased drastically in the 20th century due to human activities:^[1,3,4] Syvitski et al.^[3] estimated an increased sediment load of approximately 2.3 billion metric tons per year to the earth's rivers, with much of that excess load being contained in freshwater systems due to impoundments that impede the natural flux of sediments to the oceans. What are the impacts of increased sediment load on aquatic biota and ecosystems? A number of excellent critical reviews have addressed this question, with foci ranging from terrestrial to ocean sediment flux,^[4,5] to responses of specific aquatic taxa to suspended sediments and sedimentation,^[2,6–9] and to community-level impacts.^[10,11] It is important to recognize that many organisms are adapted to relatively high sediment loads that vary through space and time; however, substantial increases over naturally experienced levels may push even those well-adapted species beyond their ability to cope with this stressor. We know from extensive research that all levels of biological organization are affected by increased sediment inputs to aquatic systems (i.e., individuals, populations, communities, and entire ecosystems) in all kinds of water bodies (e.g., streams, rivers,

lakes, reservoirs, estuaries, and coastal zones). Here, a broad overview of how aquatic organisms are affected by increased sediment loads is provided, as shown in Fig. 1.

CAUSES AND CONSEQUENCES OF INCREASED SEDIMENTARY INPUTS

The arrival, deposition, and transport of sediments in aquatic systems are natural and essential processes for ecosystem functioning.^[12,13] However, human activities have greatly increased sedimentary inputs throughout aquatic systems. Drivers of this increase include clearing of land for agriculture and poor agricultural land management, deforestation, mining, urban development, road and reservoir construction, and dredging.^[1–3,8,13,14] Such anthropogenic alterations of terrestrial and aquatic landscapes result in higher rates of soil erosion and mobilization of sediments into river catchments and ultimately to coastal marine waters. Overlaid on these human activities is global climate change,^[1] which contributes to more severe and unpredictable weather events that can further increase sediment movement to waterways. For example, in tropical areas, intense agriculture leads to higher erosion rates especially during post-drought severe rain events, changing the geomorphology of river and riparian landscapes, leading to even greater sediment loads being suddenly dumped into

Fig. 1 Graphical representation of major influences of increased sediment inputs on aquatic biota. Text in boxes describes potential physico-chemical changes caused by suspended sediments and sedimentation, and text in ovals describes potential specific effects on aquatic organisms caused by these two stressors.

Source: Adapted from Bruton^[6] ©1985 Springer and Kemp, Sear, et al.^[2] ©2011 John Wiley & Sons.

freshwaters that contain some of the highest biodiversity on the planet.^[13] This exemplifies the fact that excessive sediment inputs can alter the physical and chemical properties of water, including altered flow regimes and hydrological processes in lotic systems, decreased photic zone in lakes and coastal zones, decreased availability of dissolved oxygen, and increased water temperature.^[6,15] In addition, eroded soils carry contaminants (e.g., heavy metals and pesticides) and organic materials with them, posing another source of stress for aquatic life.

Sediment composition and particle size will, in part, determine how aquatic organisms will be affected by this stressor. The impacts of fine sediments [particles less than 2000 μm and thus including sand (<2000 to >62 μm), silt (<62 to >4 μm), and clay (<4 μm)^[14] on aquatic biota have received the greatest amount of attention, as they affect aquatic life in the form of both suspended sediments and through sedimentation. Coarse sediments also contribute to sedimentation as they tend to be deposited faster and can have profound impacts on geomorphology, especially of lotic systems, e.g., through changes in channel morphology and in the heterogeneity of available habitats.^[16] Aquatic biota in systems experiencing human-induced increases in sediment inputs must face this challenge on two major fronts: in the form of suspended sediments and through sedimentation. In both forms, the severity of impacts on aquatic biota is attributed to several key factors: concentration,

duration of exposure, composition of sediment inputs, and particle size.^[7,12,17] The fate of sediment inputs will vary across hydrological regimes (e.g. rivers vs. lakes vs. estuaries) and spatiotemporally; however, the way that individual organisms experience increased sediments in water has some generalities. The focus here is on these general trends.

SUSPENDED SEDIMENTS

Suspended sediments have a multitude of indirect and direct effects on aquatic life, such as changing the amount and color of light underwater, reducing oxygen availability, increasing water temperature, and abrasion of sensitive respiratory structures, as discussed later (Fig. 1). In general, increased suspended sediments have been reported to induce population declines at all trophic levels within aquatic systems, including phytoplankton and periphyton, submerged macrophytes, zooplankton, macroinvertebrates, and fishes and other vertebrates.^[2,6,14]

The scattering of light caused by suspended particles, which creates the muddy or turbid appearance of water, increases the attenuation of light with depth, meaning an overall reduction in the amount of light available underwater.^[15] This effectively decreases the depth of the photic zone, or that area in the water column where photosynthesis can take place. The resultant decrease in primary

productivity is considered one of the most important alterations to aquatic systems experiencing increased turbidity because it can have cascading impacts on the entire aquatic community.^[11] the reduction in the size and depth of the photic zone leads to a reduction in phytoplankton biomass, which can affect the growth and survival of invertebrates that require primary production for food, in turn impacting those animals that feed on invertebrate herbivores and so on up the food chain.^[11] This also reduces the areas where visually orienting animals can see, potentially altering behavioral interactions.^[18,19] In areas that were historically clear, reduction in light availability at depth can also have profound effects by shading submerged macrophytes, leading to their decline or even removal from the ecosystem. All of the animals dependent on macrophytes for food and shelter are again expected to be affected by this change in resources, resulting in community-level shifts from complex, diverse food webs, to simplified webs dominated by turbidity tolerant species.^[16,20]

Increased turbidity, or the scattering of light from suspended particulates, is expected to disrupt visually mediated behaviors, such as foraging, social interactions, reproduction, and predator avoidance, in aquatic organisms and in terrestrial animals that forage in aquatic habitats.^[6,18,19] Suspended sediments change not only the amount of light available underwater through scattering and absorption of light, as noted above, but can also change the spectral composition, or color, of light underwater through the wavelength-dependent scattering of light.^[21] This is why some rivers, for example, appear grayish, while others with more mineral-rich geologies might appear a cloudy red when turbid. Thus behaviors, such as finding a mate based on color pattern for species recognition,^[21] can be compromised, leading to hybridization and the loss of biodiversity. Limited work has also suggested that terrestrial-based aquatic predators (e.g., kingfishers and cormorants) will be affected by changes to underwater light, compromising their ability to efficiently find prey.^[6,18]

Another direct effect of suspended sediments on aquatic animals is the abrasive nature of some particulates. Respiration in aquatic organisms is achieved in a number of ways, including through gills or the integument. Gills are particularly sensitive respiratory structures as they are in direct contact with the external environment, meaning that any particulates in the water column will be filtered across sensitive structures, potentially leading to abrasion or clogging. High concentrations of suspended particulates can lead to increased mucus surrounding gills and damaged gill lamellae that could directly impair oxygen uptake and potentially impact metabolically challenging activities such as swimming.^[2,6,9] Physical damage of respiratory structures caused by suspended particles has a serious physiological cost for the animal, as the ability to uptake oxygen is compromised. Evidence suggests that such physiological stress can lead to lowered body condition, reduced growth,

hyperplasia, respiratory impairment, reduced tolerance to disease and toxicants, and death.^[6,10]

High suspended sediment loads and sediment resuspension can, in addition to compromising respiration via abrasion of gills, reduce oxygen availability due to high oxygen sequestration capacity of sediment particles^[6] and increased temperature through the absorption of light energy.^[15] The creation of hypoxic (low dissolved oxygen) zones has serious negative impacts on aquatic communities, with mass fish kills the most obvious.^[20] Oxygen availability in water is much lower than in air (~1% in water vs. ~21% in air) and so many aquatic organisms are adapted to acquire oxygen under these circumstances (e.g., through gills or their integument). However, even small changes in oxygen availability can create physiological stress for many aquatic organisms, and a concomitant increase in temperature can exacerbate this problem in ectothermic animals. As an example, ectothermic fishes that experience increased ambient temperature will have increased metabolic demands, thus requiring more oxygen. If the warmer water also has less dissolved oxygen, the fish will not be able to meet their metabolic demands, possibly leading to death.^[22]

Many fishes maintain a top trophic position in aquatic food webs and are of high economic importance; therefore, they have been extensively studied in the context of responses to increased suspended sediments.^[2,7] Freshwater fish biodiversity, in particular, has decreased drastically, in part attributed to increased sedimentary inputs.^[20] These declines are likely due to both direct effects of sediments on fish (e.g., gill clogging) and indirect effects (e.g., reduced growth due to declines in food availability). Extensive experimental work examining the mechanisms by which suspended sediments might lead to fish population declines show a suite of traits that can be negatively impacted. For example, work on economically important salmonids (e.g., trout and salmon) has shown reductions in foraging rate and efficiency, growth rate, respiratory and physiological stress, altered behavior (e.g., reproductive, homing, and predator avoidance), and egg and larval mortality.^[2,6,7] Additional responses of fish generally include reduced toxicant tolerance, elevated stress hormones, disrupted growth and development, and population declines.^[2,6] While fish responses were highlighted here, other obligate aquatic vertebrates (e.g., amphibians) likely respond in similar ways to increased suspended sediment loads.

As more experimental work is performed on fishes, some ambiguity has been reported in species-specific responses to increased suspended sediments. For example, the “level” of turbidity or concentration of suspended particles varies widely across studies and responses, with some fishes responding lethally to very minor increases in turbidity, and others not responding in any negative way to very high suspended sediment loads.^[2,12] In some fishes, moderate increases in turbidity may impart a short-term benefit because scattered light creates a background against

which planktonic prey contrast strongly over short distances,^[9] making them easier to find. The same principle may also make it more difficult for top predators to find their fish prey at longer distances. Although only a few studies have directly tested this idea, it is only expected at low-to-moderate levels of turbidity.^[23] The long-term effects of moderate increases in turbidity on respiration and community dynamics, as examples, are not known.

In general, few studies have tested the full suite of factors imposed by suspended sediments on fish and other aquatic animals, or the synergistic effects of concentration, duration, composition, and particle size. It is clear from the literature that fishes and macroinvertebrates^[17] show species-specific responses to increased suspended sediments; however, proximate mechanisms underlying the link between turbidity and fish population declines are potentially complex and not well understood.^[7]

SEDIMENTATION

Many of the sediments deposited into waterways will sink to the substrate through the process of sedimentation. The effect of sediment deposition on aquatic life can be as dramatic as when sediments are suspended and has been well studied for benthic communities.^[9,12] Sedimentation is considered a major factor in the degradation of riverine habitats resulting in the loss of benthic biota.^[9,14] The major habitat changes associated with sedimentation, such as burial, filling of interstitial spaces, and reduction in oxygen availability, are discussed later.

The rate of sedimentation depends on a number of physical characters of the sediments and the hydrology and geomorphology of the water body. For example, silt deposition in fast flowing streams will be slower than in low-flow areas, such as behind impoundments (e.g., dams). Stream geomorphology is often altered as a result of sedimentation and results in what was a heterogeneous river (with riffles, pools, submerged structure, etc.) becoming a channelized and homogenized habitat lacking essential resources for many rheophilic and structure-loving animals.^[16] The removal of heterogeneous patches will greatly diminish the complexity of benthic communities of plants and animals and may provide the opportunity for non-native invasive species to infiltrate the altered habitat.

As benthic substrate is inundated with sediments, periphyton growth is reduced (i.e., due to covering of substrate and/or lack of light for photosynthesis), thereby decreasing the food supply for many benthic organisms. In addition, settlement and attachment of periphyton or other sessile organisms (e.g., corals, sponges, and mollusks) are prevented by the covering of suitable hard substrate by sediments. At the same time, interstitial spaces become filled. These spaces, found under and between benthic substrate such as cobble, are required for the persistence of many benthic invertebrates and the eggs and

larva of fish and amphibians, as they provide refuge from predators and nursery grounds.^[6,9,10,17] Changes in the invertebrate and fish communities reflect changes in habitat heterogeneity (e.g., as patches required by some species are lost) and also reduced oxygen availability (depending on the organic content of sediments).

The smothering action of sedimentation on the physical structure of the benthic habitat also functions to smother aquatic organisms via clogging of the gills and integument, thus reducing oxygen uptake. For example, demersal adhesive fish eggs have a sticky coating that will bind sediments falling out of suspension, effectively creating a hypoxic situation in which obtaining oxygen for routine metabolic function is diminished.^[7] The physiological costs associated with decreased capacity to obtain oxygen can lead directly to death in organisms not able to compensate, e.g., by moving away from areas of high sedimentation. The eggs and larva of many fish species are susceptible to this smothering action, resulting in high levels of mortality.^[2,6,7] This loss of early life history stages in many species likely scales up to population declines, although direct tests of this link are scarce.

CONCLUSION

The effects of increased sedimentary input into earth's waters highlight the critical idea that what we do on land will influence water quality and aquatic ecosystem functioning. All levels of biological organization in aquatic habitats and those in surrounding terrestrial habitats can be impacted by human-induced sediment movement to aquatic systems. Mitigation and management of land- and water-based activities will be important as we move forward. For example, where dredging activities take place on a regular basis, accounting for fish spawning seasons and the effects of sediment influx through resuspension and subsequent falling out of suspension on eggs and larvae might be particularly important.^[8] An interesting example of such considerations is the removal of dams no longer in commission, which has instigated new research to understand how the potentially sudden release of impounded sediments will influence both the physical and biological properties of rivers and downstream ecosystems.^[24] The spatial (e.g., downstream) and temporal (e.g., long-term) impacts of dam removal on aquatic communities are only beginning to be understood.^[24]

It is clear that increasing the amount and type of suspended sediments and sedimentation in aquatic systems will have profound influences on aquatic organisms. Considerable evidence suggests that changes in sedimentary inputs from the terrestrial to aquatic environments can drastically alter the community dynamics within aquatic ecosystems and may have cascading effects on riparian zones.^[13] Linking the mechanistic effects, such as abraded gills and physiological stress, with population declines and

community-level effects is required to fully understand the processes by which altering the terrestrial landscape will affect entire aquatic ecosystems at local and global scales.

Sedimentation Control and Erosion: Engineering Techniques

Jose Miguel Reichert

Federal University of Santa Maria, Santa Maria, Brazil

Elemar Antonino Cassol

*Department of Soils, Federal University of Rio Grande do Sul (UFRGS),
Porto Alegre, Brazil*

Abstract

Engineering techniques for soil erosion/sedimentation control involve manipulation of surface topography and usually are complex and costly to install and maintain, thus requiring proper planning and implementation. However, they are essential for controlling and orienting the flow of excess water generated in agricultural, forest, pasture, or urban land and should be used in conjunction with agronomic and management practices.

INTRODUCTION

Water erosion is caused basically by raindrop impact and runoff of excess water (Fig. 1), thus erosion and sedimentation control strategies must be based on covering the soil against raindrop impact, increasing water infiltration to reduce runoff generation, and increasing surface roughness to reduce overland flow velocity. To pursue these objectives, several strategies (Fig. 2) can be adopted, including agronomic measures, soil management, and mechanical or engineering methods^[1,2] as discussed and illustrated in this entry.

Erosion is a natural process, which cannot be completely controlled, but engineering methods can help in reducing erosion rates to maintain a maximum sustained level of production while keeping soil loss below a threshold (soil loss tolerance). Erosion control is also needed to reduce nutrient and pesticide losses, to prevent pollution of surface water, and to avoid sedimentation or siltation of water bodies.

It is largely accepted that soil management and agronomic measures are more suitable for erosion control because of lower cost and greater effect on reducing soil detachment due to surface protection, increased water infiltration, and runoff reductions and are easily incorporated into existing and improved farming systems,^[3] with characteristics of sustainability.

ENGINEERING TECHNIQUES

Practices of engineering erosion control include contouring, terraces, contour barriers and stone terraces, waterways, conservation structures, gully stabilization structures, and geotextiles.^[1–3]

Contouring

Contouring consists of performing all field practices such as plowing, disking, planting, and cultivation on the contour

(Fig. 3). It is effective for low slopes and short slope length and for rainstorms of low intensity. The effectiveness of this practice is about 50%^[2] depending upon slope grade and length, and this effectiveness can be increased by establishing a series of depressions or pits (Fig. 4), which fill with water and sediment during rain.

Terraces

Terraces are mechanical structures constructed across a slope and consist of a channel and an earth or stone bank to intercept surface runoff, allow it to infiltrate and evaporate or divert the excess to a stable outlet at a non-erosive velocity. Depending upon their function or type of construction, terraces are classified as retention or absorption, diversion or graded, and bench terraces. Retention or absorption terraces are used when water is to be stored on the hillside of slopes less than 4.5°, having level channels able to accumulate runoff volume generated by a 10-yr return period rainfall (Fig. 5). Diversion or graded terraces aim at intercepting runoff and conduct it to a proper outlet through a channel of a slight grade, usually 1:250 (Fig. 6) on slopes less than 7°. Bench terraces are used on steep slopes, up to 30°, alternating a series of shelves (cuts) and raises (fills; Fig. 7). Research data from several authors^[1] indicate an effectiveness in soil loss control of bench terraces up to 93%. Terraces must be properly designed to avoid even greater soil erosion damage,^[2] and should be planned considering the whole farm, a group of neighboring farms, or even a small hydrographic catchment,^[3] to ensure optimization of landuse.

Contour Ridges and Stone Terraces

Contour ridges are earth banks, similar to narrow-based terraces, constructed across the slope using hand tools,

Fig. 1 Rill and interrill erosion and sedimentation because of improper soil conservation in southern Brazil in the early 1970s.

Fig. 2 Agricultural field with agronomic and engineering soil conservation methods in southern Brazil.

Fig. 3 Contouring in an agricultural field in southern Brazil.

animal traction implements, and sometimes motorized farm machinery. These structures are frequently used on small-scale farms and hilly regions. Their effectiveness in reducing soil loss varies but research data from several authors indicate values up to 80% and even 100% control.^[1] Contour stone bunds (Fig. 8) are an alternative technique on stony lands, where stone walls are set up in shallow trenches. These allow slow retention of sediment and are permeable to water. With time, upslope sedimentation will generate a gradual development into bench terraces. The construction of stone barriers requires considerable labor and time but is more permanent and easier to maintain than earth barriers.^[3] Spacing and construction details are presented by FAO.^[3]

Fig. 4 Sedimentation pits in a horticultural field in Costa Rica.

Fig. 5 Retention or absorption terraces in southern Brazil, accumulating runoff in a level channel.

Waterways

A system of graded terraces requires waterways to receive the excess drained runoff and safely conduct at a non-erosive velocity to lower parts of the landscape. Waterways must be carefully established (considering location, construction, and stabilization) and maintained (managing grass species and controlling incipient erosion) to avoid serious erosion problems, even causing gully formation. Grass waterways

Fig. 6 Diversion or graded terraces in southern Brazil.

Fig. 7 Bench terraces on high-grade hillslope in Guatemala.

Fig. 8 Contour stone barriers in an agricultural field in Cape Verde.

(Fig. 9), tile drains, or on steep slopes, concrete structures (Fig. 9) are located in natural depressions or, if needed, reshaped channels. The grass waterways reduce water flow velocity because of the retardance effects of vegetation and increased soil resistance to erosion due to soil coverage and aggressive rooting system holding soil particles together. To work properly, waterway design follows defined principles from channel hydraulics,^[1,4] and the flow ways must be maintained and cared for.^[3]

Fig. 9 Grass waterway draining to a concrete drop inlet structure in southern Brazil.

Fig. 10 Conservation structures showing drop spillway and flumes to convey water downslope, along with stone barriers, in Spain.

Conservation Structures

In certain situations, the only feasible way to convey safely large amounts of runoff water from a higher elevation to a lower one is through the use of conservation structures that are made of some type of non-erodible material, such as concrete or large rocks. Examples of these structures include chute drop inlets (Fig. 9), flumes and drop spillways (Fig. 10), and pipe spillways, which must follow standard functional requirements to maintain channel stabilization.^[4] Selection and design of these structures are based upon existing or anticipated erosion problem, slope steepness, estimated maximum water flow discharge, and cost of alternative systems. Conservation structures are usually used in conjunction with other erosion control techniques such as grass waterways (Fig. 9).

Gully Stabilization Structures

Gullies represent an advanced stage of rill erosion (Fig. 11) and are most important as a source of sediment

Fig. 11 Gully development on sandy soil in southern Brazil.

in streams. If the gully is small, recovery might be suitable by filling it with soil, but in many cases, recovery is technically and economically not viable. In such cases, gully stabilization is recommended by constructing small dams using diverse materials depending on availability. These materials may include stones, wood planks or branches, earth, etc., to trap sediment, thus reducing gully depth and slope. Along with these stabilization structures, plants must be established to reclaim the affected areas (Fig. 12). Sometimes, to control the overfall of water on the headwall on large gullies, more permanent structures are required.^[1,2]

Geotextiles

Erosion on road baks or urban areas is best controlled by vegetation but establishment on these highly erodible and usually infertile soil surfaces is difficult. Thus, other materials including straw and hay to help establishing vegetation are used but these do not hold tight to the soil and are washed away easily.^[2] Alternative materials include geotextiles that are permeable textiles for erosion control interacting with soil and vegetation. The geotechnical material is in the form of a mat, sheet, grid, or web of natural or synthetic fiber.^[1] The first type is biodegradable while the second type gives a more permanent protection to a slope, interacting with roots to improve soil cohesion and slope stability.

Fig. 12 Gully stabilization with used tires, stones, and vegetation in Costa Rica.

CONCLUSION

Engineering techniques vary in their purpose and suitability. For a given field condition, a variety of methods should be considered and adopted in an integrated manner, depending on whether water or wind erosion is the most prominent problem. Technology, money, and labor availability are also constraints in adopting a given method; thus, for different locations around the world, myriad ways of adaptation are developed and used by professionals and farmers.

Seepage

Patricia M. Gallagher

Drexel University, Philadelphia, Pennsylvania, U.S.A.

Abstract

Seepage is a complex process that can be difficult to quantify and analyze. In certain situations, such as flow through dams, simple analysis methods may be employed. More complex analysis is required for applications such as developing and managing groundwater resources. The difficulties associated with measuring the hydraulic conductivity accurately and accounting for the inherent variability of natural soil deposits is the most challenging aspects of seepage analysis.

INTRODUCTION

The term *seepage* is used to describe the flow of water through the subsurface. Soil formations consist of soil particles with interconnected voids; seepage occurs through the voids. Seepage is important in engineering applications because it affects the stability of dams and levees, as well as dewatering of excavations during construction. Additionally, since groundwater is often used for water supply and irrigation, it has to be protected from overuse and contamination. This entry provides a brief overview of seepage principles and applications. For more detailed information, see the studies by Cedergren,^[1] Coduto,^[2] Driscoll,^[3] Duncan,^[4] Fetter,^[5,6] Freeze,^[7] and Harr.^[8]

Water reaches the soil when precipitation percolates through the unsaturated zone under gravity flow until it reaches the *water table* or *phreatic surface*, which is the top of the zone of saturation and may vary seasonally. Once the water reaches the phreatic surface, seepage is typically horizontal through the soil. Eventually, the groundwater recharges streams and rivers or may be pumped from the ground as a water supply.

The quantity and speed of flow through a soil formation depend on the size of the voids through which the water flows. There are essentially two types of soil deposits as follows: sand and clay. Sand deposits have bulky particles and larger voids than clay deposits, so that more water tends to flow faster through sand than through clays. Deposits that readily transmit water are called aquifers, while aquiclude permit very little flow. Clays are often used as barriers to flow, e.g., in dams or as compacted liners while sand deposits often function as water-supply aquifers.

SEEPAGE PRINCIPLES

Water, both static and flowing, affects stresses and stability in soil. The static water pressure below the groundwater

table increases linearly with depth according to the following relationship

$$u = \gamma_w z \quad (1)$$

where u is the water pressure (lb/ft² or kN/m²), γ_w is the unit weight of water (lb/ft³ or kN/m³), and z is the depth beneath the groundwater table (ft or m). When water pressure is described as $z = u/\gamma_w$, it is called pressure head.

For water flowing through the subsurface, the total energy potential is a combination of pressure head, elevation head, and velocity head. Total head can be calculated using Bernoulli's equation as follows:

$$h = \frac{u}{\gamma_w} + z + \frac{v^2}{2g} = \text{constant} \quad (2)$$

where h is the total head, or the sum of the energy potentials, u is the water pressure (lb/ft² or kN/m²), z is the elevation head (ft or m), v is the water velocity (ft/s or m/s), and g is the gravity (ft/s² or m/s²). The velocity of groundwater is generally so small that velocity head can be considered to be zero for most flow problems.

While the total energy is constant at any point in the region of flow, the viscous resistance within the pores of the formation causes a loss of energy across the region of flow, described as *head loss*, Δh , as shown in Fig. 1. In Bernoulli's equation, the energy between points A and B can be written as follows:

$$\frac{u_A}{\gamma_w} + z_A = \frac{u_B}{\gamma_w} + z_B + \Delta h \quad (3)$$

where Δh is the total head loss over the flow distance ΔL .

The ratio of head loss to the flow distance is called the *hydraulic gradient*,

$$i = \frac{\Delta h}{\Delta L} \quad (4)$$

Fig. 1 The illustration of head loss between two points in a soil mass.

While the velocity head can usually be considered zero in Bernoulli's equation, the flow velocity is very important for determining the quantity of flow moving through the soil formation. Darcy's law is used to relate the flow of water through soil to the hydraulic gradient as follows:

$$v = ki \quad (5)$$

where v is the Darcy velocity or specific discharge (ft/s or m/s) and k is the hydraulic conductivity (ft/s or m/s).

The *Darcy velocity* is actually a quantity rather than a velocity, so it is more correctly called the *specific discharge* or *flux*. It accounts for the quantity of flow traveling through the entire cross-sectional area of flow, including both soil particles and voids. The *seepage velocity*, v_s , is the velocity at which water actually moves through the area occupied by the pore spaces. Therefore, it is always larger than the Darcy velocity. The area occupied by the pore spaces is typically quantified in terms of *porosity*, n , the ratio of the volume of voids to the total volume. Porosity ranges from about 25% to 50% for most soil deposits. The Darcy velocity and the seepage velocity are related by the porosity as follows:

$$v = v_s n \quad (6)$$

Darcy's law, which is valid for most types of soil formations, is the basic equation used to describe groundwater flow.

HYDRAULIC CONDUCTIVITY

Hydraulic conductivity, a measure of water's ability to move through the soil, is the proportionality constant that

relates the Darcy velocity to the hydraulic gradient. It describes the properties of both the formation and the fluid moving through it. A second parameter, *intrinsic permeability*, K , describes the properties of the media, such as the grain size and the tortuosity of the flow path. The hydraulic conductivity and the intrinsic permeability are related by the following equation:

$$k = K \frac{\rho g}{\mu} \quad (7)$$

where ρ is the density of the permeant (kg/m^3) and μ is the viscosity of the permeant (Pa s or cP).

Hydraulic conductivity is highly variable spatially due to the heterogeneous nature of soil deposits and/or the presence of discontinuous layers or faults. Additionally, hydraulic conductivity varies with the direction of flow and can vary by orders of magnitude over the distance of a few inches or feet, even in soil deposits that appear to be fairly homogeneous. The hydraulic conductivity is a function of the void ratio and the grain size distribution of the formation. In general, sands have much higher hydraulic conductivity values than clays and can transmit large quantities of water. Typically, hydraulic conductivity values of coarse sands and gravels are in excess of $>10^{-3}$ m/s; fine sands range from 10^{-3} m/s to 10^{-5} m/s; silty sands range from 10^{-5} m/s to 10^{-7} m/s; silts range from 10^{-7} m/s to 10^{-9} m/s; and clays tend to be $<10^{-9}$ m/s.

Hydraulic conductivity can be measured in either the laboratory or the field. Laboratory tests are done on small samples in a controlled environment, so while they may give accurate values, they cannot capture the variability of a deposit. Field methods may provide a better overall idea of the hydraulic conductivity of a formation, but they are expensive and can be difficult to interpret.

Two types of laboratory tests are commonly used to determine the hydraulic conductivity. The constant head test is used on highly permeable soils such as sand or gravel. The falling head test is more suitable for measuring the hydraulic conductivity of less permeable soils such as silt and clay. In both tests, the flow of water through a specimen of known area is measured, and Darcy's law is used to calculate the hydraulic conductivity.

Field tests typically require several wells, including a central pumping well and surrounding observation wells. Water is pumped out of the pumping well, and the water levels in the observation wells are measured when steady conditions are reached. The interpretation of pump tests is based on certain simplifying assumptions; if these assumptions are not valid for the formation in question, the results may be questionable. Single wells may also be used to measure the hydraulic conductivity. The tests are done by causing an instantaneous change in the water level through either

addition (a slug test) or removal (a bail test) of a known volume of water. The time taken by the water level to recover is measured and used to calculate the hydraulic conductivity. There are also indirect methods of assessing the hydraulic conductivity, including correlations based on the grain size distribution of the formation.

APPLICATIONS OF SEEPAGE THEORY

Dams and Levees

Dams are used for a variety of reasons, including flood control, water supply, and storage of liquid wastes. Levees are used primarily for flood control. Seepage through and beneath dams and levees is an important consideration in design. The primary concerns in seepage analysis are as follows: 1) the amount of seepage that will go through or beneath the structure; 2) the potential for erosion and piping at the downstream end; and 3) the uplift pressure acting underneath the structure. If a dam is used for water supply, care must be taken to limit the amount of seepage through or beneath the dam since water flowing beneath the dam cannot be used as water supply.

The simplest method for analyzing the flow through or beneath a dam is a *flow net*. An example of a flow net is shown in Fig. 2. A flow net is a graphical solution to the Laplace continuity equation, which describes steady flow in the x and y directions as follows.

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} = 0 \quad (8)$$

As shown in Fig. 2, the solution consists of the following two families of mutually perpendicular lines: 1) *flow lines*, which show the path water travels along and 2) *equipotential* lines, which show the contours of total head. Rules for drawing flow nets can be found in most textbooks on introductory soil mechanics. Computer programs may also be used to solve the Laplace equation, but the flow net is simple to use and, considering the uncertainty associated with the determination of the hydraulic conductivity, often accurate enough for most engineering analyses.

Fig. 2 Example flow net.

The flow net can be used to calculate the total head and the water pressure at any point beneath the structure, the seepage quantity, and the risk of damage to the dam from erosion and piping. Piping is the loss of soil from beneath the dam. If enough soil is removed through erosion, channels can form in the foundation, allowing uncontrolled flow of water beneath the dam and often failure. Erosion is most likely to occur where the hydraulic gradient is the highest, typically where the water exits from beneath the structure. If erosion is a problem, solutions include lowering the upstream water level, placing a filter at the downstream end of the dam, and increasing the length of the flow path by placing an impermeable layer at the upstream edge of the dam.

Water Supply and Groundwater Contamination

Groundwater must be properly managed as a resource. Aquifers are often the source of drinking and irrigation water. If overpumped, resources could be depleted, causing loss of water supply, loss of base flow to streams, or salt-water intrusion in areas near coastlines. Additionally, since groundwater contamination can affect water quality, it is necessary to protect against it.

Aquifers are either confined or unconfined. An unconfined aquifer is one in which the water level is below the top of the soil formation, so the water is under atmospheric pressure. If more water flows into the aquifer, the water level will rise. In contrast, a confined aquifer is one in which the top boundary is aquiclude, confining the water in the aquifer and causing it to be under pressure. If a well is drilled into a confined aquifer, the water will rise above the top of the aquifer. If the water flows to the ground surface, the well is called artesian.

Although groundwater modeling is a complex 3-D problem, there are some simple analyses for modeling the flow of water to a single well. For a confined aquifer (Fig. 3), the flow rate (Q) from the well may be calculated using the following equation:

Fig. 3 Well in a confined aquifer.

Fig. 4 Well in an unconfined aquifer.

$$Q = \frac{2\pi k H_a (h_0 - h_w)}{\ln\left(\frac{r_0}{r_w}\right)} \quad (9)$$

where H_a is the aquifer thickness, r_0 is the drawdown radius, h_0 is the water height at r_0 , r_w is the well radius, and h_w is the water height at well.

For an unconfined aquifer (Fig. 4), the equation for water quantity is as follows:

$$Q = \frac{\pi k (h_0^2 - h_w^2)}{\ln\left(\frac{r_0}{r_w}\right)} \quad (10)$$

While these simple equations are useful to demonstrate the factors that influence flow to a well, most groundwater modeling requires the use of numerical codes. The complexity of subsurface conditions, the heterogeneity and anisotropy of the parameters involved in modeling, and the uncertainty of the measurements make groundwater modeling extremely difficult.

As water resources dwindle and contamination affects the quality of drinking water supplies, proper management of groundwater resources becomes more important. Groundwater contamination can be caused by leakage from underground tanks, by solid waste landfills or lagoons, and by deep-well injection of liquid wastes. In addition, animal wastes, fertilizers, and pesticides may leach into the soil and contribute to groundwater contamination. The movement of contaminants through the subsurface depends on the type present.

Contaminants that dissolve in the groundwater are carried along with the flowing groundwater by the processes of advection, the bulk flow of contaminants along with the flowing groundwater, and dispersion, the spreading out of the contaminant in front of the advancing contaminant front. Dispersion is caused by the variation in pore size in the formation.

If contaminants are lighter than water and insoluble, they will float on top of the water table. These types of

contaminants are called light non-aqueous phase liquids. Contaminants that are heavier than water and insoluble (dense non-aqueous phase liquids) tend to sink to the bottom of the aquifer and get into larger pores and fractures. These types of contaminants can be very difficult to locate and treat.

Dewatering

Dewatering is another important application of seepage principles. When excavations are required below the groundwater table, dewatering is used to remove water from the excavation, so that construction can occur in the dry. The basic types of construction dewatering methods include open pumping, predrainage, and cutoffs. Selecting an appropriate method of dewatering depends on numerous factors, including the hydraulic conductivity and soil conditions, the depth of the excavation below the groundwater table, and the size of the excavation. It can be a complex problem and is typically left to specialty dewatering contractors.

Open pumping consists of controlling the water from the excavation using trenches and sumps. The water is directed to the sumps through the trenches and removed from the excavation by pumping from the sumps. It is a simple method of dewatering and is most suited for use in excavations where the amount of flow is small. In cases where the hydraulic conductivity is high and large amounts of water could flow into an excavation, predrainage may be used. Predrainage is used to intercept the groundwater before it reaches the excavation by pumping from wells or well points placed around the perimeter. It can involve pumping large quantities of water and has the potential to alter the regional groundwater level. In areas where the flow of water through the soil is significant, it can be difficult to keep an excavation dewatered. In cases like this, cutoffs may be used to prevent the water from entering the excavation. A cutoff, or seepage barrier, is designed to minimize the flow of water into an excavation. Typical examples include sheet pile walls and slurry walls. A slurry wall is a trench filled with a soil-bentonite backfill. It is excavated using a bentonite slurry to support the trench walls and then filled with a backfill that has a low hydraulic conductivity. Seepage barriers can be very effective in reducing the amount of water that can flow into the excavation.

CONCLUSION

Seepage is a complex process that can be difficult to quantify and analyze. In certain situations, such as flow through dams, simple analysis methods may be employed. More complex analysis is required for applications such as developing and managing groundwater resources. The

difficulties associated with measuring the hydraulic conductivity accurately and accounting for the inherent variability of natural soil deposits remain the most challenging aspects of seepage analysis.

Selenium

Gunnar Gissel-Nielsen

Head of Program Plant Ecosystems, Riso National Laboratory, Roskilde, Denmark

Abstract

Selenium (Se) has been recognized as an essential mineral in human and livestock nutrition for more than 30 years but never proved to be essential for plants. Lack of Se in food has often been viewed as an example of a mineral imbalance related to intensive crop production as the main source of Se for animal and humans in the soil–plant system. This entry explains why field treatment with Se is an inexpensive, safe, and easy way of ensuring a desirable Se intake in humans and animals.

INTRODUCTION

The traditional definition of a plant nutrient is an element essential for the growth and development of plants. However, with the increasing concern on the quality of agricultural crops as animal and human food, elements or compounds that improve the quality should be considered as plant nutrients, too. A clear example is selenium (Se).

GEOGRAPHICAL DISTRIBUTION OF Se

The lower and the upper limits for adequate Se supply are approximately 0.05 mg/kg dry matter and 2 mg/kg, respectively.^[1] Outside Europe, crops containing toxic Se concentrations are found in the mid-western regions of the U.S. and Canadian prairies, in Venezuela, India, and China. Se deficiencies are more common and have been reported in both western and eastern coastal areas of North America, Venezuela, Australia, New Zealand, Japan, and China. However, no information is available about the Se status of most countries of the world. In Europe, Scandinavia is a natural low-Se area, while Central Europe ranges between deficiency and sufficiency. Se toxicity has only been observed in a few spots of Wales, Eire, and Russia.^[2]

Blood Se content is correlated with Se concentrations in the food for both humans and animals. Cereal and vegetables are dominant Se sources in the human diet and, along with pasture plants, in livestock fodder; the Se intake can be estimated to a great extent by evaluating the Se uptake by the fodder crops grown in the area in question. Consequently, an increase in the Se concentration of crops is an obvious way to remedy Se deficiency in humans or livestock (Fig. 1).

Se UPTAKE BY PLANTS

Low-to-moderate soil Se is not correlated with plant Se because of the large number of other factors influencing

the availability of soil Se to plants. In soils with high pH, inorganic Se occurs mainly as selenate, which is not fixed in the soil. Consequently, if precipitation and leaching are low, crops will be rich in Se. This is known in some places in India and in South Dakota, U.S.A.^[3] On the other hand, a low pH favors the selenite form, which is fixed strongly to the soil clay particles and iron hydroxides. Consequently, soils with similar Se content will produce crops with much lower Se content in low pH soils than in high pH soils. Volatile Se is lost to the atmosphere through microbial activity, but Se also returns to the soil from the atmosphere through precipitation. This leaves only a minor part of Se in the cycle to pass through the plant–animal system.

The Se concentration in plants also depends on the time of sampling. The release of Se from clay and organic matter is a slow process. Se released during the winter is available for crops during spring when the yield of grass is low, giving a relatively high Se concentration. When the growth of grass increases during summer, less Se is available and it is distributed over a far greater yield. Therefore, the Se concentration drops as a result of dilution.

FIELD TREATMENT WITH Se

Different ways of raising Se concentrations of crops have been investigated over the years. Of all the different ways, the application of selenate to the soil and foliar application of selenate or selenite are those of practical importance. Pre-sowing treatment of barley (*Hordeum vulgare* L.) and soybean (*Soya hispida* L.) seeds with selenite and selenate has also been tested.

Soil Application

The initial studies on soil application of Se involved spraying of selenite or selenate solutions onto the soil

Fig. 1 Possible cycles of Se under field conditions with morainic soils.

Source: From Gissel-Nielsen, Gupta, et al.^[1]

surface in 1967.^[4,5] These relatively simple experiments showed the promising effects of Se addition, and they have been followed by comprehensive studies worldwide.^[2] Different Se salts have been tested in pot and field experiments. Selenates in general are 20 to 50 times more available than selenites, at least in the first year.^[1]

A large-scale field experiment involving an annual addition of 60 and 120 g Se/ha for 5 years as Na_2SeO_3 incorporated in a NPK compound fertilizer was carried out on 21 Danish farms in 1972–1973.^[3] The soils were all glacial deposit mineral soils with a pH of 5–7. The 120 g Se treatment raised the native Se concentration of 0.02–0.04 mg/kg of a number of fodder crops to 0.08–0.13 mg Se/kg, considered a sufficient and safe level for animal nutrition. Other experiments showed a similar effect when about 10 g Se/ha as selenate is added.

A strip of a paddock (5% of the area) was supplied with 340 g Se/ha, which is equivalent to 17 g Se/ha for the total area. The grazing sheep had the same blood Se content as sheep grazing a paddock with the even distribution of Se. The free movement of the grazing animals compensates for an uneven distribution of Se.^[2] For perennial pastures, a single application of 100 g Se/ha can give a desirable residual effect for 4–5 years.

Flue gas desulphurization waste, fly ash, and sewage sludge are examples of alternative sources of Se for field crops. They all resulted in varying increases in the Se concentration of crops. In most cases, the amount of waste needed for remedying a Se deficiency situation was so high that other problems occurred, such as too high cadmium concentrations or salinity problems. These waste products, therefore, could be acknowledged to have a positive effect on the Se concentration of crops when deposited in the field, but they should not be considered Se fertilizers as such.^[2]

Foliar Application

The complication of soil effect on the availability of added Se can be avoided by using foliar application. In a test of foliar applications of up to 50 g Se/ha as selenite in field experiments with spring barley, a linear correlation was found between added Se and Se concentration in the plants. Five to ten grams of Se per hectare resulted in the desired minimum level of about 0.1 mg/kg Se in the grain. The increase in Se concentration was greater in the mature grain than in the straw, indicating an effective translocation of the absorbed Se to the edible part of the plant. The addition of a detergent to the Se solution improved the efficiency of foliar application, giving the desirable minimum concentration of about 0.1 mg/kg in the grain using 2–5 g Se/ha. The foliar application was performed at two growth stages (end of May and end of June). The late application also resulted in a twofold Se increase. The likely explanation is a better plant cover of the soil and thereby a greater part of the solution wetting the leaves.^[2]

In another field experiment, foliar application in the spring of 10 g Se/ha as sodium selenite to an established pasture resulted in concentrations within the desirable range in all cuts during the growing season. The recovery of the added Se in crops was up to 35%.

Comprehensive Finnish field experiments included foliar applications of selenite and selenate. The results were in accordance with the earlier Danish studies: selenate is somewhat more effective than selenite, an amount of 5–10 g Se/ha is sufficient, and the effect depends on the stage of development of the crop at the time of spraying.^[6]

Seed Treatment with Se

Seed treatment with Se has been tested in barley and soybean.^[2,7] The amount of selenite needed to obtain a desirable Se concentration in harvested barley grain was the same as when selenite was added through the fertilizer. The pre-sowing treatment of barley seed with selenite resulted in a concentration of several 100 mg Se/kg seed making it highly toxic to animals and humans.

Experience on a Larger Scale

In Finland, field treatment with Se is performed to an extent that enables the study of overall long-term effects. Since 1985, all Finnish commercial fertilizers for food and feed crops are enriched with sodium selenate: 16 mg Se/kg fertilizer for cereals and horticulture crops and 6 mg Se/kg fertilizers for fodder beets and grass production. The Se concentrations in crops are monitored carefully, and Se content in all crops is elevated, typically from about 0.01 to 0.1–0.3 mg/kg dry matter.^[8]

It was decided to remove fertilizers containing 16 mg Se/kg from the market, leaving only those having 6 mg/kg for all crops. This change stabilized the average Se concentrations of Finnish crops at a somewhat lower level: about 0.1–0.2 mg/kg in cereal grain and about 0.13 mg/kg and 0.17 mg/kg in hay and grass silage, respectively. In 1998, the Finnish authorities decided to increase the Se content of fertilizers to 10 mg Se/kg. In any case, Finland has become a country producing crops with adequate Se levels for livestock and human nutrition instead of being a Se-deficient area.

Risk Assessments

A number of experiments were carried out to study possible harmful effects on the environment from using Se-enriched fertilizers. Fishes in lakes and streams, animals living in the soil or in the fields, or birds did not concentrate the added Se to any harmful level.^[2]

Main Guidelines

All these experiments lead to the following conclusion: Foliar application of about 5 g Se/ha as selenite or selenate and soil fertilization using about 10 g Se/ha as selenate, or about 120 g Se/ha as selenite, are effective annual treatments for raising the Se content of annual crops to a desirable level for human and animal nutrition. The effect of Se is enhanced when it is used with a detergent for foliar application, and for all treatments, the effect is the greatest when carried out on a well-established crop. The residual effect of these treatments is very small. A somewhat higher amount is needed for pasture crops, but this gives a residual effect lasting 2–3 years.

BIOAVAILABILITY OF Se

Whether Se is offered in premixed fodder, concentrates, mineral supplements, water, lick stones, or ruminant pellets, it occurs as inorganic selenite, whereas the Se in crops occurs predominantly as free seleno-amino acids or in proteins.^[2] Organic Se is often found to be more effective than inorganic Se to prevent Se deficiency in livestock. However, the significance of organic versus inorganic Se in animal nutrition is subject to much discussion, so one cannot recommend a single Se compound as the best in all situations.

It is well established that the bioavailability of different Se compounds varies greatly, and this has been shown in several experiments. Such variation stresses the importance of the form of Se in animal and human foodstuffs, and research has been carried out to evaluate the factors that influence the chemical form of Se in plants.

Earlier short-term experiments carried out with tomato roots (*Lycopersicum esculentum* Mill.) and other experiments with maize (*Zea mays* L.) showed that Se is translocated in the xylem sap as selenate when added to the nutrient solution as selenate, whereas selenite is metabolized immediately to seleno-amino acids and translocated as such.^[2]

To evaluate the significance of these findings, rye grass (*Lolium perenne* L.) and barley supplied Se as selenite or selenate through the roots or by foliar application in a pot experiment.^[2] A series of fractionations of Se compounds in grass and barley grain separated the compounds into total and water-soluble Se proteins, seleno-amino acids, selenite, and selenate. Neither the oxidation state of the added Se nor the method of application had any significant effect on the distribution of Se in the various compounds. In all four cases, only about 10% of Se was present in an inorganic form. This implies that any method of supplementing crops with inorganic Se leads to the same Se compounds in the mature plants. Therefore, the effect of different methods can be evaluated purely on the basis of total uptake as a percentage of the total added.

CONCLUSION

Se toxicity in humans and livestock is rare, and only China has reported severe cases of deficiency leading to the death of many humans. Contrary to this, moderate Se deficiencies leading to problems in animals are seen in many countries, and these deficiencies might be more dangerous to human health than often considered. As described earlier, in view of the high rates of cardiovascular disease and certain forms of cancer in Finland at the time, the Finnish authorities legislated the introduction of selenate in all compound fertilizers sold in Finland since 1985. In New Zealand, selenized compound fertilizers are available, and in some countries (e.g., Sweden and the United Kingdom), microelement solutions including Se are on the market for foliar application. In many countries, premixed feed enriched with inorganic Se is available for livestock production. This reflects the growing concern for Se deficiency.

Se is available in tablet form for human consumption in most countries, and in general a much more varied diet including relatively Se-rich foodstuffs such as fish and some vegetables are consumed by humans, but far more attention is paid to the Se nutrition of animals than to the human population. It is likely that increased attention will be paid to the importance of sufficient Se in human diets as well as in livestock feed. The fact that a reasonable Se supplementation of crops is an inexpensive, safe, and easy way of ensuring a desirable Se intake in humans and animals has been shown in this entry.

Serpentinitic Soils

Rebecca Burt

National Soil Survey Laboratory, U.S. Department of Agriculture—Natural Resources Conservation Service (USDA-NRCS), Lincoln, Nebraska, U.S.A.

Michael A. Wilson

U.S. Department of Agriculture—Natural Resources Conservation Service (USDA-NRCS), Lincoln, Nebraska, U.S.A.

Abstract

Serpentinitic soils develop from metamorphosed (serpentinized) ultramafic rocks. Primary mineral constituents are antigorite, chrysotile, and lizardite. While serpentinitic soils compose only small, widespread parts of the earth's surface, they have unique properties that dramatically alter productivity and land use compared to other soils. Elemental deficiencies, imbalances of major elements, and enrichments of nickel, chromium, and cobalt influence plant survival and productivity. Landscapes with these soils typically have sparse, low productive stands of shrubs and other diverse flora, and are not practical for agricultural production. These unique properties have warranted inclusion of specific taxonomic categories on soil classification systems and continue to generate interest of research scientists worldwide.

INTRODUCTION

Serpentinite is a rock consisting primarily of serpentine minerals, e.g., chrysotile, lizardite, and antigorite, with the generalized chemical formula $[\text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4]$, derived from the alteration (serpentinization) of such minerals as olivines, pyroxenes, and amphiboles in dunites, peridotites, pyroxenites, and other ultramafic rocks.^[1] Lizardite and antigorite have platy morphology, whereas chrysotile has tubular or fibrous morphology. Fibrous chrysotile is a mineral of the asbestos group^[1] and is known to cause serious human-health problems.^[2,3]

U.S. *Soil Taxonomy*^[4] identifies serpentinitic soils at the family level as having magnesian mineralogy “any particle-size class, except for fragmental, with >40% by weight magnesium (Mg)-silicate minerals, such as serpentine minerals (antigorite, chrysotile, lizardite) plus talc, olivines, Mg-rich pyroxenes, and Mg-rich amphiboles, in the fine-earth fraction (<2 mm).” With little substitution of iron (Fe) for Mg in serpentine, Fe in peridotite minerals is incorporated into common accessory minerals such as magnetite and hematite.^[5]

IDENTIFICATION OF SERPENTINE MINERALS

Serpentine minerals present quantification problems by X-ray diffraction (XRD) or optical analysis without labor-intensive pretreatments to remove Fe oxides from mineral surfaces. Oxides attenuate peaks during XRD analysis and

mask mineral grains during optical analysis of sands or silts, preventing proper identification. Additionally, crystalline units of individual serpentine minerals are generally below the observational limit of the optical microscope, and two or more mineral species are often intermixed in sand-sized grains.^[6,7] This characteristic thus requires the use of an electron microscope for exact mineral identification and limits the utility of the optical microscope in quantification of individual mineral species. Thermogravimetric analysis (dehydroxylation at 600–650°C) and total analysis are other methods used in the identification and quantification of serpentine minerals,^[8] typically requiring no pretreatments and allowing determination on the entire <2 mm fraction.

SOIL PROPERTIES

Ultramafic rocks occupy <1% of the land surface of the earth but are found in many parts of the world, e.g., North America, Europe, continental Asia, Japan, Australia, New Zealand, Africa, Brazil, Puerto Rico, and Cuba.^[9] “Serpentine barrens” is a common term for soils developed from ultramafic (serpentinized) rock.^[10–12] Serpentinic soils are recognized for their unusual, diverse, and sparse flora.^[9] Vegetation on these soils has been linked to nutrient deficiencies and imbalances [low nitrogen (N), phosphorus (P), and potassium (K); adverse calcium (Ca)/Mg ratios], non-anthropogenic metal enrichments [Nickel (Ni), chromium (Cr), and cobalt (Co)], low-water holding capacity,

and susceptibility to erosion, with resulting slope instability and/or land sliding.^[13–18] Vegetation on serpentinic soils in the Siskiyou-Klamath Mountains of southwest Oregon is reduced in kind and number, relative to surrounding landscapes, with broad-leaved trees typically absent and shrubs and pines of greater importance.^[12]

Fertility studies of serpentinic soils documented Ca/Mg ratios <0.7 ^[9,13,19,20] as unfavorable for the growth of most plants.^[21–23] Plant deficiencies of Ca can be the result of low Ca and/or excess Mg, antagonistic to the uptake of Ca by plants.^[24] Low Ca^{2+} can also result in lowered ability to counteract the adverse effects of such ions as Na^+ , Mg^{2+} , and H^+ .^[25,26] In a study of 22 soils on serpentinized peridotite in California,^[14] productivity (timber-yield index) was related more to Ca/Mg ratio in surface horizons than to any combination of climatic and physical soil variables or Fe, manganese (Mn), Cr, Ni, or Co content. Research on associated mafic and serpentinic soils in Maryland found extractable Ca/Mg ratios <0.10 and has a 98% probability of having formed from serpentine rather than from non-serpentine mafic parent materials.^[27] A Ca/Mg ratio <0.1 is used in the Magne-sic Great Group in the Australian Soil Classification System,^[28] but this ratio has to be incorporated into U.S. *Soil Taxonomy*.^[4,12]

High levels of Ni, Cr, and Co in some serpentinic soils have been linked to potential toxicity and/or antagonistic effects on other ions.^[9,23,29,30] Many studies have focused on Ni because of characteristic symptoms exhibited in plants growing on these soils.^[31] Ni substitutes for Mg in the serpentine crystal structure^[5] and is generally considered a more likely candidate for chemical toxicity because of its greater availability to plants than Cr and because of its greater abundance than Cr and Co, respectively.^[9] A study of serpentinic subalpine soils in Switzerland^[32] showed exchangeable $\text{Ni} > 0.1$ mmol/kg and exchangeable $\text{Cr} < 0.01$ mmol/kg. Most Cr was located in the structure of primary minerals (e.g., garnet, pyroxene, and spinels) and secondary minerals (Fe oxides). However, research on serpentinic soils in northwest Spain^[33] showed the foliage of some agricultural crops (e.g., sugarbeet, cabbage, and pasture) accumulates considerable Ni and Cr, despite low to moderate ethylenediaminetetraacetic acid-extractable amounts of both elements in the soils.

Field observations of ultramafic rocks often indicate widely differing weathering rates within the same general area.^[19,34] Elemental distribution (e.g., Mg, Ni, and Cr) and mineral alteration have been used as indicators of pedogenesis of ultramafic soils. As Mg leaches from the soil profile, elements such as Fe, Al, and silicon (Si) may concurrently be enriched.^[35] Ni, Co, and Mn generally increase with depth, except in the driest environments, whereas Cr is less mobile, tending to accumulate in upper parts of the soil profile, associated

with high levels of Fe oxides.^[32,36] Mineral transformations during pedogenesis of ultramafic soils are determined by factors such as topography and the climate. Smectite formation is promoted on wetter landscape positions and concentrated in soils on footslope and toe slopes as opposed to higher landscape positions.^[37,38] Similarly, the formation of Mg-rich smectite in poorly drained landscape positions has been attributed to neo-synthesis in an environment with high pH and accumulations of Mg and Si by subsurface flow of soil water.^[39] A pedogenic study of ultramafic soils along a climatic gradient in southwestern British Columbia shows nearly equal proportions of hydroxyl-interlayered vermiculite/smectite, chlorite, serpentine, and talc in the wet-cool zones, whereas serpentine, talc, chlorite, and only small amounts of smectite are found in the dry-cool zones.^[40] In a soil catena on serpentine in northwestern Italy, serpentine minerals appear to weather to low charge vermiculite in upper and drier horizons or to smectite in poorly drained conditions.^[41]

MANAGEMENT STRATEGIES

Timber on some serpentine soils^[42] (Curry County Oregon Soil Survey; U.S. Department of Agriculture, Natural Resources Conservation Service, unpublished) is considered impractical to manage because of low productivity and sparse stands, owing to inherent infertility and nutrient imbalance, complicated by susceptibility to landsliding and erosion. However, other studies^[14] suggest that on some old peridotite terrains, which are at least partially serpentinized, the timber may be as productive as timber on some soils on more silicic (less mafic) rocks in the area. Little information exists on agricultural soils, and the effect of their management on heavy metal availability,^[31,33] owing partly to the limited agronomic use of these soils.^[9,33] Some studies^[33] have shown, however, that despite moderate amounts of soil-extractable heavy metals, crops such as cabbage (*Brassica oleracea*), barley (*Secale cereale*), and pasture grown on managed serpentinic soils can accumulate significant amounts of Cr and Ni, with sugarbeet (*Beta vulgaris*) accumulating dangerous levels of Ni. Some management strategies that help reduce plant availability of Ni and Cr include liming and additions of organic matter, other plant nutrients (N, K, and Ca), and phosphate fertilizers.^[43–46]

CONCLUSION

Serpentinic soils develop from metamorphosed (serpentinized) ultramafic rocks. Primary mineral constituents are antigorite, chrysotile, and lizardite. While serpentinic soils compose only small, widespread parts of the earth's surface, they have unique properties that dramatically alter productivity and land use compared to

other soils. Elemental deficiencies (e.g., N, P, and K), imbalances of major elements (e.g., Ca/Mg), and enrichments of Ni, Cr, and Co influence plant survival and productivity. Landscapes with these soils typically have sparse, low productive stands of shrubs and other diverse flora, and are not practical for agricultural production. These unique properties have warranted inclusion of specific taxonomic categories on soil classification systems and continue to generate interest of research scientists worldwide.

National Soil Survey Center, U.S. Department of Agriculture—Natural Resources Conservation Service (USDA-NRCS) (Retired), Fayetteville, Arkansas, U.S.A.

Abstract

Oxides, oxyhydroxides, or hydroxides (referred to collectively as oxides) of iron (Fe), aluminum (Al), and manganese (Mn) are termed sesquioxides. Oxide minerals largely affect soil chemical and physical properties, morphology, and classification. These minerals occur in soils as cations in fourfold (tetrahedral) and eightfold (octahedral) coordination with oxygen and hydroxyl groups. Substantial ionic substitution occurs in these minerals mostly due to the ability of many cations to reside in octahedral coordination. Most oxide minerals in soils form pedogenically after the release of these elements from primary mineral weathering, but a few Fe (e.g., magnetite) and Al (e.g., corundum) oxide minerals are predominantly of primary origin (inherited from the parent material). Some oxide minerals require an oxidizing (well-drained) soil environment for stability (e.g., most Fe and Mn oxides), while others do not (Al oxides). Virtually all soils possess sesquioxide minerals, with the possible exception of extremely young soils, extremely calcareous soils, or soils that possess seasonal high water tables for extended periods. In seasonally wet soils, the transformation and translocation of the redox sensitive Fe and Mn result in soil wetness (redoximorphic) features that are used to evaluate depths to seasonally high water tables. Fe oxides in particular, and Mn oxides in some instances, impart much color to soils. Substantial coulombic and specific adsorption of organic molecules, cations, and anions occur on sesquioxides.

INTRODUCTION

Research suggests most sesquioxides possess no permanent charge but develop surface charge dependent on the pH and ionic strength of the soil environment. Readers are encouraged to consult these following sources for additional information: Hsu,^[1] Schwertmann and Taylor,^[2] and McKenzie.^[3]

IRON (Fe) OXIDES

Fe Oxide Minerals

Most Fe oxides in soils form by pedogenic processes. In an oxidizing environment, Fe released from the weathering of primary minerals such as hornblende and biotite coordinates octahedrally with oxygens and/or OHs to form Fe oxide minerals. Goethite (α -FeOOH) and hematite (α -Fe₂O₃) are common hexagonal close-packed Fe oxides. Because Al³⁺ is similar in size to Fe³⁺, substantial aluminum (Al) substitution occurs in both of these minerals.^[2] The cubic close-packed lepidocrocite (γ -FeOOH), a polymorph of goethite found in periodically saturated soils, tolerates little Al substitution within its structure. Ferrihydrite, a para-crystalline Fe oxide, along with amorphous Fe

forms, is generically called “soil Fe.” No consensus on the formula and structure of ferrihydrite and other “soil Fe” phases exist, but it is believed these forms control Fe activities in soil solutions. Ferrihydrite is also considered a necessary precursor to hematite formation. Magnetite (Fe₃O₄) is a primary mineral, and most evidence suggests that it oxidizes to maghemite (Fe₂O₃) in soils. This oxidation may be facilitated in near-surface environments by fire,^[4] although most Fe oxides that possess some degree of magnetism, magnetite, and maghemite exhibit the strongest magnetic properties.

Properties of Fe Oxides

The amount and type of Fe oxide dictate subsurface soil colors because their fine-grained nature and charge properties allow them to coat other soil minerals. Red soil colors are due to the presence of hematite, yellow to brown colors indicate the presence of goethite, and orange colors arise from the presence of lepidocrocite (Table 1; Fig. 1A). Fe oxide color is also dependent on crystal size, degree of crystallinity, and the amount of ionic substitution (mostly Al) within the mineral structure.^[2] Soil colors are often the result of mixtures of Fe oxide minerals, and certain Fe oxides (e.g., hematite)

Table 1 General properties of oxide minerals commonly found in soils.

Element	Common oxide form in soil	Color	Soil environments	Major effects on soil properties
Fe	Goethite, α -FeOOH	Yellow to brown	Oxidizing, many environments	Color, aggregation, sorption of cations, anions, and organics
Fe	Hematite, α -Fe ₂ O ₃	Red to purple	Advanced weathering, oxidizing, warm and humid	Color, aggregation, sorption of cations, anions, and organics
Fe	Ferrihydrite, Fe ₅ HO ₈ · 4H ₂ O	Reddish-brown	Wet, rapid Fe release and oxidation, young soils	Color, aggregation, sorption of cations, anions, and organics
Al	Gibbsite, Al(OH) ₃	Colorless	Advanced weathering or rapidly leached aluminous environments	Aggregation, sorption of anions and cations
Mn	Many minerals	Black to dark brown	Oxidizing	Color, sorption of anions and cations

Source: From Schwertmann.^[5]

possess greater pigmenting ability than others.^[2] Many techniques have been developed that estimate soil Fe oxide content from either Munsell color notation or spectral reflectance values acquired via remote sensing.

Soil color is also used as a differentiating characteristic at many levels of soil classification schemes, including Soil Taxonomy. For example, Rhodic subgroups of Ultisols and Alfisols possess dark red hematite-enriched

Fig. 1 (A) Hematite (H), goethite (G), and redox depletions (D) in a plinthic Paleudult; bar = 20 mm. argillic horizons, while wet soil taxa possess features related to Fe transformations in seasonally saturated soils.

Wet Soil Features

A discussion of Fe [and manganese (Mn)] oxides is not complete without a reference to biochemical reduction effects on their solubility. Fe and Mn possess oxidation states that are dependent on the redox potential of the soil environment, which is largely controlled by soil saturation and microbial activity.^[6] When soils become saturated for significant time periods, aerobic microbes deplete the available oxygen gas (O_2) and cause oxidized soil components such as Fe^{3+} and Mn^{4+} in oxide minerals to undergo chemical reduction induced by anaerobic microbial respiration and relatively high labile organic carbon content. As Fe and Mn are reduced, the oxide minerals bearing these elements become soluble. These elements can re-oxidize as water tables recede, precipitate as reduced forms in sulfide minerals, be adsorbed onto exchange sites, or move from one part of the soil to another by mass flow and diffusion. Reductive dissolution and loss of Fe and Mn oxide grain coatings exposes the silicate minerals that are commonly gray to white, resulting in the formation of redox depletions (see redox depletion in Fig. 1A). The oxidation of Fe and Mn in another part of the soil results in Fe and Mn oxide concentrations and a general reddening to blackening of the area. These depletions and concentrations, or redoximorphic features, are commonly used to interpret the depth to a seasonally high water table in soils (Fig. 1A and B).

Chemical and Physical Properties of Fe Oxides

Fe oxides greatly influence soil physical and chemical properties due to their charge characteristics, fine-particle size, and high surface area. Generally, Fe oxides possess surfaces that protonate (gain H^+), deprotonate (lose H^+), and develop charge based on soil solution pH and ionic strength. The pH at which the negative charge equals the positive charge has been termed the point of zero charge (PZC). Soil pH levels below this point result in (+) charged oxide surfaces, while the pH levels above the PZC result in (−) charged surfaces (Fig. 2A).^[7] Fe and Al oxides tend to have higher PZCs than Mn oxides. Because the PZC of most soil Fe oxides occurs above pH 7, many soils with $pH < 7$ have Fe oxides with (+) charged surfaces. Therefore, many highly weathered soils with high Fe (and Al) oxide content have substantial ability to sorb anions on their surfaces and possess appreciable anion exchange capacity (AEC). Phosphorus (P) and other anions are also sorbed through specific mechanisms involving coordination of the anion to the Fe within the oxide mineral (Fig. 2B). Because of this, P deficiency in crop and forest

Fig. 2 Proposed mechanisms for the development of pH-dependent charge (A) and specific adsorption of oxyanions (PO_4); (B) by Fe oxides.

Source: From Schwertmann & Taylor.^[2]

production is common on soils possessing high Fe (and Al) oxide quantities.

Fe oxides also play a large role in soil aggregation. Because many Fe oxide surfaces possess a (+) charge, they tend to facilitate aggregation by forming bridges between (−) charged phyllosilicate minerals. Poorly crystalline Fe oxides may promote increased aggregation compared to more crystalline forms.^[2]

Al OXIDES

Al Oxide Minerals

Gibbsite [$Al(OH)_3$] is the most common Al oxide found in soils^[1] (Table 1). Corundum (Al_2O_3), boehmite ($AlOOH$), and diaspor ($AlOOH$) are primary minerals that are not typically found in soils but are common in bauxite ore deposits.^[1] Unlike Fe oxides, poorly crystalline phases of Al oxide have not been readily identified in soils but most likely exist. Al oxides are essentially colorless, and their visual identification in soils is difficult.

Gibbsite Formation

Gibbsite is a common constituent of tropical and subtropical soils, and its presence generally suggests an advanced stage of soil development. Gibbsite formation is mostly due to the desilication [weathering and leaching of silicon (Si)] of kaolinite or other aluminosilicate that occurs over long-term weathering under humid or extreme leaching

environments. However, in highly leaching aluminous environments, gibbsite can form rapidly.^[8] Because it can form rapidly as well as exist in transported parent materials, its presence does not always indicate an advanced degree of soil development.

Al Oxide Properties

Similar to Fe oxides, gibbsite develops surface charge based on soil solution pH and ionic strength. Most evidence suggests that Al oxides have a PZC ~pH 8.^[1] Thus, gibbsite is (+) charged in most soils and readily sorbs anions, cations, and organic molecules by both specific and coulombic attraction. The specific adsorption of ions (similar to Fe oxides) also occurs with gibbsite. Similar to Fe oxides, gibbsite contributes to soil aggregation by bridging (–) charged phyllosilicate surfaces.

Mn OXIDES

Mn Oxide Minerals

Mn ions are similar in size to Fe; thus, Mn is found in several primary minerals. However, Mn oxides are not as abundant as Fe oxides because lower quantities of Mn typically exist in parent materials. Because Mn is essential to plant growth, but high concentrations found in wet or acid soils are toxic, an understanding of its mineral forms is critical for crop management.^[3] McDaniel and Buol^[9] determined that approximately half of the Mn in soils developed from a gneiss parent material existed in oxide mineral form, while the other half was either organically bound or resided on exchange sites. Similar to Fe, most pedogenic Mn minerals exist as oxides with Mn in sixfold coordination with oxygens or OHs. Because Mn is redox sensitive, morphological features resulting from its transformations are also used as a soil wetness indicator. Mn oxides mostly exist as black, hardened concentrations, called concretions, that violently effervesce upon treatment with H₂O₂. They also commonly exist as black coatings on ped faces (Table 1; Fig. 1C).

Mn occurs in several oxidation states (Mn²⁺, Mn³⁺, and Mn⁴⁺) within oxide minerals of varying crystallinity.^[9] Mn oxides are classified as either layer or tunnel type, the difference depending on the presence or absence of tunnels within the mineral structure.^[3] Birnessite [(Na_{0.7}Ca_{0.3})Mn₇O₁₄ · 16H₂O], vernadite (MnO₂), and lithiophorite [(Al,Li)MnO₂(OH)₂] are layer-type Mn oxides that have been identified in soils, while hollandite (Ba₂Mn₈O₁₆) is a tunnel-type soil Mn oxide.^[3] Other primary Mn oxides sometimes found in soils include the tunnel-type pyrolusite (MnO₂) and todorokite [(Na,Ca,K,Ba,Mn²⁺)₂Mn₄O₁₂ · 3H₂O].^[3]

Mn Oxide Properties

Most evidence suggests that Mn oxides possess PZCs < pH 4.5.^[3] This renders most Mn oxide surfaces (–) charged except under extremely acid conditions. Cations, particularly heavy metals, are adsorbed onto Mn oxide surfaces by both specific mechanisms and coulombic attractive forces.^[3] For example, in a study of metal-contaminated soils in Colorado, zinc, cadmium, and lead were preferentially adsorbed onto Mn and Fe oxide surfaces, while copper was predominantly associated with the organic matter fraction.^[10] Mn in oxide minerals is reduced to the soluble Mn²⁺ in saturated environments by similar mechanisms as described in the Fe oxide section earlier. Soluble Mn²⁺ is either leached, sorbed onto organic or clay surfaces, or reoxidized to black concentrations.

GENERAL RELATIONSHIPS BETWEEN OXIDE MINERALS

The presence of high quantities of sesquioxides suggests an advanced degree of soil weathering. Although many soil orders possess these minerals, sesquioxides are concentrated in Oxisols and Ultisols. Because of the properties Fe and Al oxides impart to soils, these soils are often red, possess significant AEC, and are strongly aggregated. P deficiency is also common.

Table 2 Oxide dominated soil mineralogical families in soil taxonomy and their occurrence.

Mineralogical family	Criteria	Soil orders where commonly found
Ferritic	>40% Fe ₂ O ₃ in the < 2 mm fraction	Oxisols, Ultisols, Inceptisols
Gibbsitic	>40% gibbsite in the < 2 mm fraction	Oxisols, Ultisols
Sesquic	18–40% Fe ₂ O ₃ and 18–40% gibbsite in the < 2 mm fraction	Oxisols
Ferruginous	18–40% Fe ₂ O ₃ in the < 2 mm fraction	Oxisols, Ultisols
Allitic	18–40% gibbsite in the < 2 mm fraction	Oxisols, Ultisols (none currently correlated)
Ferrihydritic	(8 × Oxalate extractable Si + 2 × oxalate extractable Fe) > 5	Andisols, Spodosols
Parasesquic	>10% Fe ₂ O ₃ + gibbsite in the < 2 mm fraction	Ultisols, Alfisols, Mollisols, Aridisols, Spodosols, Inceptisols

Source: From Soil Survey Staff.^[11]

Oxide minerals can also act as cementing agents in soils. Plinthite, a common constituent of southeastern U.S. coastal plain soils, is a hardened mass of mostly Fe oxides that also typically contain quartz, phyllosilicates, and gibbsite. In large quantities, plinthite can have a major effect on soil properties and cause significant reductions in rooting depth and hydraulic conductivity.

Many soil mineralogy classes defined by oxide mineral quantities exist in Soil Taxonomy due to the influence these minerals have on soil properties.^[11] Most of the 12 soil orders have at least one soil series identified that has an oxide-dominated mineralogical class (Table 2).

Don F. Yule

Department of Natural Resources, Rural Water Use Efficiency Initiative, Indooroopilly, Queensland, Australia

Abstract

Soil shrinkage is one of the intrinsic characteristics of any soil, providing a unique insight into a soil's nature, specifically the response to change in soil water content. The nature and degree of soil shrinkage is determined by several inter-related soil properties with clay percentage, clay type, and the ratios of saturating cations predominating. Several tests are available to quantify and express this characteristic with each providing different aspects of a soil's shrinkage nature and potential. Soil classification systems are utilizing the characterization of soil shrinkage to aid in the definition of soil classes, recognizing the unique insight this provides into a soil's inherent nature.

INTRODUCTION

Soil shrinkage is the process of soil material contracting to a lesser volume, with the loss of water on drying. In agriculture, soil shrinkage is focused on two topics: the characterization and classification of soils containing clay, as the degree of shrinkage (and swelling) largely determines the potential for soil structure development,^[1] and the redevelopment of soil structure (soil resilience) compacted by wheels and implements.^[2] In engineering, soil shrinkage is a key determinant of material stability for both intrinsic and stress states associated with structures, such as foundations, pipelines, and roads, and soil conservation structures.^[3]

Negative aspects of soil shrinkage include overall volume change and uneven shrinkage of soil supporting loads in engineering and in agriculture root breakage caused by soil cracking and the super dehydration of soils from air thermals in cracks.^[4] Positive, agricultural aspects of soil shrinkage include soil cracking, providing aeration and facilitating water entry, and the formation of naturally, aggregated, fine seedbeds with wetting and drying cycles.^[5]

FACTORS AFFECTING SOIL SHRINKAGE

Many factors, singly and in combination, affect the degree of shrinkage in a soil, including soil fabric, mineralogy, saturating cation, electrolyte concentration and speciation, clay content, surface area, antecedent water content, frequency of wet-dry cycles, confining pressures, and soil

thickness.^[6] Shrinkage is positively correlated with greater total and fine clay contents, and particularly greater proportions of clay composed of expanding 2:1 clay minerals, such as the smectites.^[6] Antecedent water content is positively correlated with clay percent, i.e., the proportion of expansible clay minerals and surface area. Hence, it is also positively correlated with total shrinkage. Particle arrangement also affects shrinkage characteristics where random (edge to face) arrangements can trap larger volumes of water (or air) than stratified (face to face) arrangements, and hence have greater capacity for shrinkage.^[4] Shrinkage is reduced by factors such as increased proportions of sand relative to clay, as the interlocking of sand and silt grains increases the frictional forces,^[6] increased organic matter, as the organic matter dilutes the shrinkage potential of the mineral components,^[7] and, as cited by some studies, low cation exchange capacity and high exchangeable sodium levels.

MECHANISMS OF SOIL SHRINKAGE

Smectites, because of the charge deficiency, have strong ability to attract and adsorb water molecules onto clay domains.^[6] The mechanisms of soil shrinkage explain the loss of this water, there being two common representations (Figs. 1 and 2). The first involves the measurement of the volume of a soil sample as it slowly dries from a fully wet condition and provides a relationship between soil volume and water content (Fig. 1). This relationship is termed as a soil shrinkage characteristic curve^[8] and consists of four zones, though all four zones are not always

Fig. 1 A plot of a soil shrinkage characteristic curve showing the four shrinkage zones and the theoretical (1:1) shrinkage line.

present: structural, basic or normal, residual, and zero shrinkage.^[9] In structural shrinkage, volume change is less than the volume of water lost, arising from the drainage of large pores that do not completely close with water loss. Basic shrinkage, traditionally termed normal shrinkage, is commonly depicted as equal volume and water loss. This zone accounts for most shrinkage in agricultural soils, generally between soil water potentials of -33 to <-1500 kPa.^[10] Water is lost from space between clay domains (lumps of individual clay particles), and the random orientation of these domains cause shrinkage to be equidimensional, thereby resulting in crack formation. Residual shrinkage, like structural shrinkage, has volume change less than the volume of water lost. Water is lost from stable pores between clay particles that are unable to completely close as the particles retain the clay matrix structure. Zero shrinkage, recognized by some authors, has no volume change with water loss.^[11]

Fig. 2 Shrinkage of a soil cube showing equidimensional shrinkage, resulting in soil cracking.

On the soil shrinkage characteristic curve, the location of experimental data is referred to a 1:1 line, termed as the saturation line as it represents the shrinkage of a structureless (air-less) clay paste (Fig. 1). With reference to this theoretical line, the relative proportions of the specific volumes of the solid, liquid, and air for an experimental plotted value may be obtained.

The second representation of soil shrinkage aims to represent “whole soil” shrinkage behavior and is generally applicable to the shrinkage of large, intact soil units—either soil cores in the laboratory or field soil (Fig. 2). A measurable field result is a reduction in the vertical dimension, i.e., the soil surface moves down, and a visible field result is the formation of large cracks that form laterally at irregular intervals (Fig. 2). Importantly, the soil block between the cracks contains all the structural and residual porosity, and the cracks (including the “crack” above the soil surface) contain only the basic (or normal) shrinkage porosity.

THE MEASUREMENT OF SOIL SHRINKAGE

Soils may be characterized by measurement of total or partial shrinkage, of either linear dimensions or volume, as an initially wet sample loses water. There is no unique measure of soil shrinkage; different techniques provide different aspects of a soil’s shrinkage nature and potential.

Measurements may be made on soil in different states: 1) remolded samples of finely ground material; 2) natural soil aggregates; 3) intact blocks or cores; and 4) volume change in the field.^[12] A vital consideration is that for each of the tests, alteration of the start and end points in terms of water content will provide different results, hence negating the potential for soil comparisons.

Remolded Samples

The most common measure used in engineering applications is linear shrinkage: LS_{std} (based on the study by Standards Association of Australia^[13]). Determination is made of the percent decrease in length of a subsample of ground soil ($<425 \mu m$) that has been wet to its liquid limit, mixed to a homogeneous paste, placed in a mold, air-dried ($20^\circ C$) for 24 hours, and then oven-dried at $105^\circ C$. The LS_{std} of the specimen is

$$LS_{std} = \frac{L_s}{L} \quad (1)$$

where L is the length of the mold in millimeters and L_s is the longitudinal length of the oven-dry specimen in millimeter.

A modification to LS_{std} , toward providing a more agriculturally pertinent measure of soil shrinkage, is the modified linear shrinkage test: LS_{mod} ,^[14] where linear

shrinkage is determined on sieved (<2 mm), not remolded soil.

Natural Soil Aggregates

Several techniques are available, measuring soil volume by liquid displacement. Waterproofing coatings for the soil sample include paraffin wax, rubber balloons, and industrial resins. The most common test is the coefficient of linear extensibility (COLE),^[15] where determinations of volume change of intact soil clods are made between a moist and an oven-dry state. The test is integral in defining the Vertisol soil group.^[16]

Intact soil clods of size 0.05–0.08 m diameter are wetted on pressure plates to a specified matric potential (commonly, –33 kPa), before being coated in SARAN[®] resin. Two paired weighings are conducted—the first on the coated clod at the –33 kPa matric potential and then a second on the clod after oven-drying (105°C). The bulk density of the clod is calculated at each level of water content, and COLE is calculated as

$$COLE_{std} = 100[(BD_{OD}/BD_{33})^{1/3} - 1] \quad (2)$$

where BD_{OD} is the bulk density at oven-dry and BD_{33} is the bulk density at –33 kPa.

Several indices of soil shrinkage can be derived from the shrinkage of coated soil clods by collecting data from the whole range of the soil shrinkage characteristic curve, not one part alone as with COLE. McGarry^[17] specified 17 indices based on fitting straight lines to the shrinkage curve, and Braudeau et al.^[11] specified 13 parameters including consideration of the points of transition between the different shrinkage zones. Such indices have been used to quantify and rationalize differences in soils or treatments (e.g., see Pillai and McGarry^[12]).

Vertical Volume Change on Cores and in the Field

These measures of volume change are most commonly gained by measuring the physical dimensions of soil samples. Three types are recognized: volumetric and destructive (based on core bulk density measurements at various moisture states), non-destructive measures with dual gamma attenuation, and “1-D” measures based on monitoring surface elevation.^[18] Disadvantages with each are small cores may give non-representative sampling in cracking soils, access tubes can initiate preferential cracking of soil around the tube giving biased measures, and there are problems with relating a local surface elevation measurement with an average value of water contents collected around the gauge. New techniques employ electronic displacement transducers with block kriging interpolation to improve the precision of the water content estimates.^[18]

Table 1 Examples of classification schemes for the assessment of volume change potential based on linear shrinkage LS_{std} and COLE.

		Volume change rating
(a) LS_{std}		
Arid to semiarid climate	Humid climate	
0–0.05	0–0.12	Low
0.05–0.12	0.12–0.18	Moderate
>0.12	>0.18	High
(b) COLE		
<0.03		Low
0.03–0.06		Medium

Source: From Holland & Richards^[19] and Dasog, Acton, et al.^[20]

THE DEFINITION OF SOIL CLASSES FROM CUT-OFF VALUES OF SHRINKAGE TEST DATA

An important aim of determining shrinkage values is to define soil classes in terms of volume change activity for either engineering or soil (pedological) classifications. Engineering classes define broad categories of soil in terms of their predicted soil behavior for conservation earthworks or building foundations. Examples of the use of LS_{std} and COLE classes are given in Table 1. Holland and Richards^[19] included climatic considerations in their classification, recognizing LS_{std} becomes limiting at lower values in drier climates, as the potential for desiccation (hence shrinkage) is greater. In pedological studies (land survey and assessment), variable volume soils may be classed in terms of their potential for volume change. The aim is to provide a numeric, independent assessment of volume-change potential to replace or supplement visual assessments of crack intensity toward classifying Vertisols. For example, in South Africa, $LS_{std} > 0.12$ is required for vertic horizons and $LS_{std} < 0.12$ but > 0.08 for melanic horizons. There is also potential and a growing demand to use such classifications to express soil resiliency, i.e., a soil’s potential to self-repair soil compaction through wet-dry cycles.

CONCLUSION

“Soil shrinkage is one of the intrinsic characteristics of any soil, providing a unique insight into a soil’s nature, specifically the response to change in soil water content. The nature and degree of soil shrinkage are determined by several inter-related soil properties with clay percentage, clay type, and the ratios of saturating cations predominating. Several tests are available to quantify and express this characteristic with each providing different aspects of a soil’s shrinkage nature and potential. Soil classification systems

are utilizing the characterization of soil shrinkage to aid in the definition of soil classes, recognizing the unique insight that provides into a soil's inherent nature."

Silica: Pedogenic Accumulation

Katherine J. Kendrick

Western Earthquake Hazards, U.S. Geological Survey (USGS), Pasadena, California, U.S.A.

Abstract

Pedogenic silica is formed in arid, semiarid, and Mediterranean climates where there is adequate precipitation to mobilize the silica but not so much as to leach the silica out of the profile. In its most advanced form, it cements the soil fabric to form extremely hard horizons known as duripans or silcrete.

INTRODUCTION

Pedogenic silica is defined as silica that has precipitated in the soil environment, taking the form of opal-A, opal-CT, or microcrystalline quartz. Opaline silica, which is amorphous to poorly crystalline, is the most common form of pedogenic silica.^[1,2] Pedogenic silica is formed in arid, semiarid, and Mediterranean climates where there is adequate precipitation to mobilize the silica but not so much as to leach the silica out of the profile. Pedogenic silica accumulation has been reported throughout the Western United States, Australia, Italy, South Africa, and New Zealand.^[3] In its most advanced form, it cements the soil fabric to form extremely hard horizons known as duripans or silcrete.

SOURCES OF PEDOGENIC SILICA

Pedogenic silica is derived from two main sources. The weathering and hydrolysis of primary silicate minerals provide for the slow release of silica into solution as silicic acid. Easily weathered silicates, such as olivine and calcic plagioclase, are particularly likely to contribute silica into solution. The second source is from the weathering of primary amorphous silica, including volcanic glass and biogenic silica (e.g., phytoliths and diatoms). Such amorphous silica is the most soluble form of silica found in the soil environment. Weathering of glassy volcanic products, including ash and tephra, to release silicic acid into solution occurs readily in soils.

DISSOLUTION OF SILICA

Factors controlling the dissolution of silica include soil solution pH, the presence of organic matter, the particle size of the material, and the presence of coatings on grains. The solubility of silica is moderate throughout the pH range of most soils but is particularly high at pH values ≥ 9 , as found in sodium carbonate soil systems. Organic matter

enhances the dissolution of silica, including quartz, and impedes precipitation.^[3] The dissolution of quartz has been shown to be highest in the root zone due to organic complexation of monosilicic acid.^[4] On the other hand, organic matter may actually form a coating on opal, impeding its dissolution.^[5] Because of surface area effects, smaller particles are more susceptible to dissolution. This phenomenon accounts for the fact that quartz does not persist in the clay fraction of most soils.^[6] Aluminum and iron (Fe) oxyhydroxides can form insoluble coatings on grains, thereby decreasing rates of dissolution from those grains.^[3]

MOVEMENT AND PRECIPITATION OF SILICA

Silica is moved in solution through the soil as silicic acid. Incomplete leaching allows for the precipitation of this silicic acid in the pedogenic zone. During drying induced by evapotranspiration, silicon dioxide is adsorbed onto surfaces, forming amorphous opaline silica. This process led to the silica cementation of south-facing terrace edges on the Central California coast.^[7] Alternatively, *in situ* alteration of eolian dust to opal-A, rather than precipitation from silica in soil solution, has been proposed for duripans in Idaho.^[8] The eolian dust comprised volcanic glass and feldspars.

Conditions favoring the precipitation of silica from solution include pH values less than 7, a high available surface area within the soil fabric, and high ionic strength of the soil solution. Although a high available surface area favors precipitation, silica cementation is most common in medium-textured parent materials with abundant skeletal grains. The grain-to-grain cementation is an important component in the formation of a duripan.^[6]

Aluminum and Fe oxyhydroxides specifically adsorb soluble silica. Since these compounds are nearly ubiquitous in soils, often as coatings on other grains, they form a significant sink for the precipitation of silica on surfaces.^[3]

SILICA MORPHOLOGY

Stages of silica cementation have been defined for coarse grained deposits in arid climatic regimes.^[9] The first stage is precipitation of silica on the undersides of clasts. These are termed *pendants* and are equivalent to *opal beards* in Australian soil descriptions.^[10] Dramatic examples of opal pendants have been described in some Central Californian soils.^[11] The second stage is precipitation within the matrix, where silica forms bridging contacts between grains. The third stage is silica precipitation on all sides of the clasts, and the final stage is a laminar cap above a plugged matrix. Apart from silica precipitation on gravels, silica can cement the finer matrix materials into nodules termed *durinodes*.

Duripans are defined as soil horizons that are irreversibly cemented by various forms of silica such that they do not slake after soaking in water or hydrochloric acid.^[12] Duripans take two general forms. In Mediterranean climates, duripans often have prismatic structure and pedogenic calcite is minimal or absent.^[1] Small opal flocs within the matrix of the prisms are the precursors to durinodes. Further development of the duripan yields extensive grain-to-grain cementation in the soil matrix (Fig. 1) and silica coatings on the tops and upper sides of the prisms. Ultimately, silica laminae with platy structure cap the prismatic horizon.^[1] This is in contrast to duripans that form in arid environments, which typically have a large component of pedogenic calcite and are characterized by a platy structure throughout, with plates 1–15 cm thick.^[13] As little as 10% silicon as opaline silica is adequate to cement horizons effectively and form a fully developed duripan.^[1]

Thorough cementation of a soil horizon to form a duripan requires geomorphic stability of long duration, particularly in the absence of readily soluble volcanic ash. The ancient landscapes of Australia fit this criterion. Silica-cemented horizons in Australia are common and are referred to as silcrete, duricrust, and gray billy.^[10]

Silica cementation has also been reported in *hardsetting* soils. Hardsetting soils have one or more horizons with hard to very hard consistence when dry. This phenomenon is recognized in soils with alternating seasons of wetting and drying, primarily those in Australia. Hardsetting soils eventually slake on wetting and are thus not irreversibly cemented.^[14] Amorphous particles and coatings of silica have been documented in these soils,^[14] suggesting that silica is an important constituent in the process of seasonal cementation.^[15] The easily mobilized silica might be ephemeral and may or may not be related to incipient formation of a duripan.

Silicon and Sodium

Jian Feng Ma

Research Institute for Bioresources, Okayama University, Kurashiki, Japan

Abstract

Silicon (Si) and sodium (Na) are both beneficial elements for higher plants. Si is the second most abundant element in the earth's crust. All soil-grown plants contain Si. Na is a common element in the environment. It is well known that excess Na inhibits plant growth, but small quantities of Na are essential and beneficial for some plant species. This entry reviews the beneficial effects, use in fertilizers, and plant uptake of these two elements.

INTRODUCTION

Silicon (Si) and sodium (Na) are both beneficial elements for higher plants. Beneficial elements are defined as those for which positive effects are expressed in only certain plant species or under specific growth conditions.^[1]

SILICON

Si is the second most abundant element in the earth's crust. The concentration of Si in soil solution ranges between 3.5 and 40 mg/l. Si in soil solution is mainly present as the uncharged monomeric molecule, silicic acid $[\text{Si}(\text{OH})_4]$, when the pH solution is below 9.0. At a higher pH (>9.0), $\text{Si}(\text{OH})_4$ dissociates into silicate ions $[(\text{OH})_3\text{SiO}^{-1}]$. The solubility of $\text{Si}(\text{OH})_4$ in water is 2.0 mM at 25°C, and the polymerization of $\text{Si}(\text{OH})_4$ into silica gel ($\text{SiO}_2 \cdot \text{H}_2\text{O}$) occurs when the concentration of $\text{Si}(\text{OH})_4$ exceeds 2 mM.

Uptake, Translocation, and Accumulation of Si

All soil-grown plants contain Si. However, the Si concentration of plant shoots varies greatly between plant species, ranging from 0.1% to 10% Si on a dry weight basis. This variation is largely due to different capacities of Si uptake by plant roots. Three uptake modes have been suggested, namely, active, passive, and rejective uptake.^[2]

Active uptake

Plant species which employ active uptake of Si, such as rice, take up Si faster than water.^[3] The Si concentration in rice leaf blades can reach more than 10% Si on a dry weight basis. The uptake of Si by rice roots is inhibited by metabolic inhibitors such as 2,4-dinitrophenylhydrazine, iodoacetate, 2,4-dichlorophenoxyacetic acid, and low temperature, suggesting that Si uptake is energy dependent.^[4] This uptake system has been characterized in the

literature.^[5] A kinetic study indicated that Si uptake by rice roots is mediated by a proteinaceous transporter. The K_m value for uptake was estimated to be 0.32 mM, suggesting that the transporter has a low affinity for $\text{Si}(\text{OH})_4$. Si uptake is very rapid and not inducible. Mercuric chloride and phloretin significantly inhibited Si uptake, but 4,4'-diisothiocyanato-stilbene-2,2'-disulfonic acid and boric acid did not, suggesting that the transporter for Si contains cysteine residues but not lysine (Lys) residues, or that Lys residues, if present, are not located at sites which are important for transport activity. However, neither the gene encoding the transporter nor the transporter protein has been isolated.

Passive uptake

With the passive mode of uptake, the uptake rate of Si by plant roots is similar to that of water.^[3] The Si concentration in the shoot largely depends on Si concentration in the medium but rarely exceeds 2.5% Si. Cucumber shows this type of uptake.

Rejective uptake

Some plants, such as tomato, take up Si more slowly than water.^[3] The Si concentration in the shoots is typically lower than 0.5% Si. A rejective mechanism seems to be involved in this uptake mode although it is not well understood.

A comparative study has showed that at least two transporters (SIT1 and SIT2) are involved in Si transport from the external solution to the xylem in rice roots (Fig. 1). SIT1 is responsible for radial transport of Si from the external solution to root cortical cells, while SIT2 regulates the release of Si from cortical cells into the xylem (xylem loading).^[6] SIT1 also exists in non-Si accumulating species such as cucumber and tomato, but the density of this transporter differs among plant species, following the order:

Fig. 1 The schematic representation of Si uptake system in different plant species. Radial transport of Si includes transporter-mediated transport and passive diffusion in rice, cucumber, and tomato. Xylem loading of Si is mediated by a transporter in rice and by diffusion in cucumber and tomato. SIT1: Si transporter from external solution to cortical cells; and SIT2: Si transporter for xylem loading.

Source: From Mitani & Ma.^[7]

rice > cucumber > tomato.^[7] However, in contrast to rice, xylem loading of Si was mediated by diffusion in cucumber and tomato. It seems that xylem loading is the most important determinant of a high accumulation of Si in the shoots. The much lower accumulation of Si in cucumber and tomato could be explained by a lower density of SIT1 and defective or an absence of SIT2.

Following uptake by the roots, Si(OH)_4 is translocated to the shoot via xylem. The form of Si in the xylem has been identified as monomeric Si(OH)_4 in wheat^[8] and rice.^[9] In the shoot, Si(OH)_4 is concentrated through the loss of water and is polymerized. The process of Si polymerization converts Si(OH)_4 to colloidal Si(OH)_4 and finally to silica gel with increasing Si(OH)_4 concentration. In rice plants, more than 90% of total Si in the shoot is present in the form of silica gel, while the concentration of colloidal plus monomeric Si is kept below 140–230 mg Si/l.^[3] A similar pattern of accumulation is observed in cucumber leaves, although the total Si concentration of cucumber is much lower than that of rice.

Si is deposited as a 2.5- μm thick layer in the space immediately beneath the thin (0.1 μm) cuticle layer, forming a cuticle–Si double layer in leaf blades of rice.^[10] There are two types of silicified cells in rice leaf blades, namely silica cells and silica bodies or silica motor cells (Fig. 2).^[3] Silica cells are located on vascular bundles and are dumbbell-like in shape, while silica bodies are in bulliform cells of rice leaves. The silicification of cells proceeds from silica cells to silica bodies. In addition to leaf blades, silicified cells are also observed in the epidermis and vascular tissues of the stem, leaf sheath, and hull of rice.

As there is no evidence that Si is involved in metabolic activities of plants, silica gel deposited on tissue surfaces is proposed to play an important role in alleviating biotic and abiotic stresses. The accumulation of Si in the shoots is a prerequisite for the beneficial functions of Si.

Beneficial Effects of Si

Positive effects of Si have been observed in a number of plant species, including rice, wheat, and barley.

Fig. 2 Silica cell (A) and silica body (B) in rice leaf blades.

Source: From Ma, Miyake, et al.^[3]

Fig. 3 Effect of Si application on the growth of rice. Rice was cultured in a nutrient solution with or without 1.67 mM Si as Si(OH)_4 .

The beneficial effects of Si differ between plant species. Beneficial effects are usually obvious in plants which actively accumulate Si in their shoots (Fig. 3). The more the accumulation of Si in the shoots, the larger is the effect that is gained. This is because most effects of Si are expressed through the formation of silica gel, which is deposited on the surface of leaves, stems, and other organs of plants. On the other hand, the beneficial effects of Si vary with growth conditions. The effects

are usually expressed more clearly when plants are under abiotic or biotic stresses. In addition, Si is the only element which does not damage plants when accumulated in excess. This is because $\text{Si}(\text{OH})_4$ remains undissociated at physiological pH and is also due to silica polymerization. Neither binding to cellular substances nor the creation of high osmotic pressure occurs in plants, even when accumulation is up to 10% Si on a dry weight basis. The beneficial effects of Si are outlined in Fig. 4.

Si-stimulated photosynthesis

Si deposited on the leaf blade keeps the leaf erect, thereby improving light interception by the leaf blade and indirectly stimulating photosynthesis. This is particularly important in dense plant stands when nitrogen (N) fertilizers are heavily applied to minimize mutual shading.

Si-decreased susceptibility to disease
and insect damage

It is well known that Si application reduces the severity of fungal diseases such as blast and sheath blight of rice, powdery mildew disease of barley and wheat, and vermin damage of rice by the plant hopper in the field. In addition

Fig. 4 The uptake, distribution, and accumulation of Si and its beneficial effects on crop growth in relation to biotic and abiotic stresses.

Source: From Ma, Miyake, et al.^[3]

to species with an active Si uptake mode, it was also reported that Si prevents powdery mildew disease of solution-cultured cucumber and muskmelon.^[11]

It has been reported that the foliar application of Si is effective in inhibiting powdery mildew development on cucumber, muskmelon, and grape leaves.^[12,13] Foliar applied Si may deposit on the surface of leaves and play a role similar to Si transported from the roots. This approach may be particularly useful for crops with passive or rejective Si uptake modes.

Si deposited on the tissue surface is proposed to be responsible for the protective effects of Si against biotic stress. The deposited Si prevents physical penetration by insects and/or makes the plant cell less susceptible to enzymatic degradation by fungal pathogens. It has been reported that Si application resulted in a stimulation of chitinase activity in cucumber and the rapid activation of peroxidases and polyphenol oxidases after infection with *Pythium* spp.^[14] Glycosidically bound phenolics extracted from Si-treated plants when subjected to acid- or beta-glucosidase hydrolysis displayed a strong fungistatic activity.

Si-increased resistance to climatic stress

Si application reduces injury to rice caused by climatic stresses such as typhoons, low or high temperature, and low light. Typhoon damage usually results from lodging and sterility. The deposition of Si in rice increases the thickness of the culm wall and the size of the vascular bundle and can help to prevent lodging. Si deposited at the hull decreases the transpiration of panicles by about 30% at either milky or maturity stage (Table 1)^[3] and prevents excess water loss. This is the means by which Si application can significantly increase the percentage of ripened grain.^[15]

Low temperature during summer can cause serious damage to rice crops. Low temperature decreases Si uptake by rice, and insufficient sunshine lowers the Si/N ratio in rice, which can lead to an outbreak of blast disease. The application of Si under such conditions remarkably reduces the incidence of blast in rice.

Table 1 Effect of Si application on transpiration of the panicle at different stages.

Treatment	Transpiration (mg H ₂ O/g fresh wt. 1 hr)		Si concentration in hull (%)
	Milky stage	Maturity stage	
+Si	204	39.2	6.36
–Si	279	50.4	0.18
+Si/–Si	1.37	1.29	

Note: The excised panicles, with or without Si supply, were placed in an incubator at 30°C, relative humidity of 30% for 1 hour.

Source: From Ma, Miyake, et al.^[3]

The positive effects of Si under low-light conditions are particularly evident. Si effects on rice growth under shading treatment are greater than for a non-shaded treatment.^[3] However, the mechanism responsible for this phenomenon is unknown. It has been hypothesized that Si deposited on the leaf epidermal system might act as a “window” to facilitate the transmission of light through photosynthetic mesophyll tissue. However, evidence supporting this hypothesis is not available.^[16]

Si-alleviated water stress

Si can alleviate water stress by decreasing transpiration. The transpiration of leaves is mediated through stomata and the cuticle. Rice plants have a thin cuticle, and the formation of a cuticle–Si double layer significantly decreases cuticular transpiration. The transpiration of rice decreases with increasing Si concentration in the shoot.^[3] Water stress causes stomatal closure and consequently decreases photosynthetic rate. Therefore, Si stimulates the growth of rice more under water-stressed conditions (low humidity) compared to non-stressed conditions (high humidity).

Si-alleviated mineral stress

Mineral stress can be either a deficiency of an essential element or an excess of an essential or other element. Many reports have shown the beneficial effects of Si under various mineral stresses including phosphorus (P) deficiency, excess of P, and toxicity of aluminum (Al), Na, and manganese (Mn).^[3]

Beneficial effects of Si under P deficiency stress have been observed in many plants, including rice and barley. Si does not have any effect on the availability of P in soil.^[17] The beneficial effects of Si on growth under P deficiency stress appear to result from decreased Mn and Fe uptake and thus increased P availability within P-deficient plants.^[18,19]

Si decreases P uptake when its supply is high.^[13] This phenomenon has been observed in rice and some non-Si accumulators such as tomato, strawberry, cucumber, and soybean.^[3] In rice, the organic P component is not affected by Si, but cellular inorganic P is significantly decreased by Si when P is supplied at high concentrations (0.7 mM).^[18] Therefore, stress caused by excess P can be alleviated by Si-induced decrease in P uptake.

Beneficial effects of Si under salt stress have also been observed in rice.^[20] The Na concentration in the shoot is decreased by about 50% with Si amendment. The translocation of Na to the shoot is partly regulated by transpiration. Since Si decreases transpiration, it is suggested that beneficial effects of Si during salt stress result from decreased transpiration.

Alleviative effects of Si on Mn toxicity have been reported in water-cultured rice, barley, bean, and pumpkin.^[3] Three different mechanisms seem to be involved,

depending on the plant species. In rice,^[21] Si reduces Mn uptake by promoting the Mn-oxidizing power of the roots. In bean, it was found that Si does not reduce Mn uptake but minimizes damage by effecting the homogenous distribution of Mn in the leaf blade.^[22] In a cultivar of pumpkin, Si causes localized accumulation of Mn around the base of trichomes.^[23]

Alleviative effects of Si on Al-induced inhibition of root elongation have been reported in many crop species, including maize, cotton, rice, teosinte, sorghum, and wheat.^[24] The formation of non-toxic Al-Si complexes in the culture solution and/or interaction between Al and Si within the plant have been suggested to be the mechanisms for this alleviative effect.^[25]

Silicate Fertilizers

In 1955, Si was first recognized as a fertilizer in Japan. Since then, 1.5–2.0 tons/ha of silicate fertilizers have been applied to paddy soils in Japan leading to a significant increase in rice production.^[2] Si fertilizers are also widely applied in Korea, China, and the United States. Various Si fertilizers have been developed including slags, which are by-products of the iron (Fe) manufacturing industry (mainly containing calcium silicate), and Na and potassium (K) silicates. The solubility of these fertilizers and their availability to plants vary greatly. They are used as a basal dressing or for topdressing. K and Na silicates are also used as foliar sprays for plants which are not able to take up Si via the roots.

SODIUM

Na is a common element in the environment. The content of this element in the earth's crust is about 2.8%, and Na concentrations in soil solutions range from 0.4 to 150 mM Na, depending on soil type. It is well known that excess Na inhibits plant growth, but small quantities of Na are essential and/or beneficial for some plant species.

Essentiality of Na

Certain plant species using the C₄ photosynthetic pathway (C₄ and CAM plants) require Na as an essential element. In these plants, Na deficiency causes chlorosis, necrosis, and decreased growth. Na is supposed to play a significant role in the conversion of pyruvate to phosphoenolpyruvate (PEP) in the mesophyll chloroplasts.^[26] PEP is the first product of carbon fixation in C₄ plants. Failure to regenerate the PEP from pyruvate will result in decreased photosynthesis in C₄ plants. A cotransporter of pyruvate/Na was found in mesophyll chloroplasts of *Panicum miliaceum*,^[27] suggesting that Na is involved in the transport of pyruvate from bundle sheath cells to mesophyll chloroplasts. In some plant species such as *Amaranthus tricolor* L., Na

Table 2 Effect of Na addition on plant growth and Na accumulation in two strains of tomato cultivated under low K stress.

Strain	Plant dry weight (g)		Na accumulation (mg/plant)
	–Na	+Na	
576	1.06	1.67	9.9
546	0.80	0.85	2.9

Source: From Figdore, Gerloff, et al.^[28]

enhances growth by stimulating nitrate uptake and reduction.^[29] Since only trace amounts of Na are required for its function in plants, Na deficiency rarely occurs in nature.

Beneficial Effects of Na

Beneficial effects of Na on plant growth are observed under both K deficiency and with optimal K supply. Under K deficiency, Na is able to act as a substitute for some functions of K such as charge compensation and osmoregulation. The K content required for optimal growth decreases from 4.3% to 1.0% in lettuce.^[30] However, the extent of beneficial effects of Na under low K stress differs between plant species. Na addition under low K stress is effective in rice, barley, and cotton but not in corn, potato, or soybean.^[1] The substitution capacity of Na also differs between cultivars within a species. The high Na substitution capacity of some strains of tomato is associated with a high accumulation of Na in the top under low K stress (Table 2).^[28] However, the beneficial effects of Na in these plant species are not apparent when K supply is sufficient.

On the other hand, in particular plant species, a beneficial effect of Na under optimal K supply is observed. This effect is not attributed to a partial substitution of Na for K, but for the stimulation of cell elongation and maintenance of water balance, although the exact mechanism is unknown. A typical example is sugar beet. Usually, Na concentration in plants is less than 10% of K levels, but in sugar beet, the Na concentration is similar to or greater than K, and increased Na enhances sugar beet growth.^[1]

Na Fertilizers

The application of Na may be effective for some plant species (e.g., natrophilic species) under K deficiency conditions. Na chloride or sulfate has been applied to sugar beet stands.^[1] Na fertilizers are also used to increase the Na content of forage and pasture plants for animal nutrition.

Slaking, Dispersion, and Crust Formation

Hwat Bing So

School of Agriculture and Food Sciences, University of Queensland, St. Lucia, Queensland, Australia

Abstract

The nature of soil structure is that it conveys specific properties to the soil, and any alteration such as the breakdown or structural development will affect the physical properties of the soil. The particles and aggregates of a soil are arranged in a hierarchical order where the lower orders tend to have higher densities and greater internal strength than the higher orders. Slaking (breakdown of the higher order: macroaggregates to microaggregates) and dispersion (breakdown of the lower order: microaggregates to particles) are the fundamental processes that are the cause of most of the soil physical problems encountered in the field that affects plant growth and soil behavior, such as waterlogging, reduced infiltration, crusting, hardsetting, compaction, poor timing of farming operations, and poor germination and establishment. Although generally perceived as distinctly different problems in the field, they can be corrected and managed using the same techniques, i.e., the prevention or suppression of the processes of slaking and dispersion in these soils. These measures include the use of organic ameliorants, the introduction of grasses into the crop rotation, and the use of gypsum and lime.

INTRODUCTION

Soil structure is generally defined as the arrangement, orientation, and organization of the primary particles of sand, silt, and clay into compound aggregates, which exhibit properties that are unequal to the properties of a mass of non-aggregated material with a similar texture. Therefore, the nature of soil structure is that it conveys specific properties to the soil, and any alteration, i.e., breakdown or structural development, to the soil structural units will affect the physical properties of the soil.

ORGANIZATION OF SOIL PARTICLES AND AGGREGATES

The aggregation and organization of the soil particles tend to form a hierarchical order^[1,2] where the lower orders tend to have higher densities and greater internal strength than the higher orders. A schematic diagram of the hierarchical nature of soil structural elements in a clay soil is given in Fig. 1.^[1] Clay particles tend to form domains (packets of parallel clay sheets, generally consisting of 5–7 sheets), and in turn, several domains form clusters, followed by several orders of clusters, i.e., microaggregates and macroaggregates. The hierarchical nature implies that the destruction of a lower order will result in the destruction of all higher hierarchical orders. An example is the dispersion of sodic clay domains, which results in the destruction of all higher orders, resulting in a dense soil with low hydraulic conductivity (K). Hence, the clay domains are the fundamental

building blocks of the soil, and its integrity may determine the soil's physical properties and behavior.

MECHANISMS OF SLAKING, DISPERSION, AND CRUST FORMATION

Soil aggregates break down in response to an external force or energy source such as tillage or raindrop energy or internally generated forces such as when aggregates are subjected to rapid wetting, with the latter being the most common cause occurring in the field. Upon rapid wetting, aggregates break down in two stages. The first is “slaking” where macroaggregates break down into microaggregates (approximately 20–250 μm in diameter). The second stage is “dispersion” where the microaggregates break down into individual particles of sand, silt, and clay.^[3] The result of these processes is the formation of a surface seal at the soil–air interface, associated with an increased packing density of the soil particles and a reduction in pore sizes. These, in turn, give rise to a reduced K or infiltration rates. Upon drying, the surface seal dries out into a surface crust. Surface sealing and crusting is a common phenomenon with cultivated soils (Fig. 2). When slaking and dispersion occur throughout the surface horizon following wetting, the whole surface horizon experienced an increased packing density and a reduction in pore sizes. In cases where the surface horizon hardens rapidly following drying, the soil is referred to as hardsetting.^[5,6] These soils are associated with high contents of silt and fine sand, which do not readily form aggregates.

Fig. 1 Hierarchical organization of particles and structural elements.

Source: Adapted from Dexter.^[1] ©1988.

Slaking of the surface soil is not necessarily a detrimental process. In its virgin state, the surface soil of self-mulching Vertisols slakes upon wetting followed by surface sealing, which breaks into small aggregates when dry and forms a mulch layer. These are highly productive soils. However, when slaking is followed by dispersion, the soil's productivity is generally reduced associated with the lowered soil K, which in turn limits the supply of water to the root zone.

Mechanisms of Slaking

Slaking following rapid wetting is the result of the following three distinct processes:

1. Softening of bonds;
2. Differential swelling following wetting of the aggregates from the outside: The stresses formed between the swelling outer layers and the inner parts of the aggregates result in the successive disintegration of the outer layers of the aggregates, which are readily observable when dropped in water; and
3. Increased pressure within entrapped air pockets from the tensions exerted by the water meniscus: Combined with the softening of the bonds, this pressure results in visually observable mini explosions of the soil aggregates when dropped in water.

Mechanisms of Dispersion

Dispersion is the result of swelling pressures derived from the osmotic pressure difference between the ion concentrations within the diffuse double layer between the clay particles and the external solution created by the addition of water. Dispersion occurs when the swelling pressure (the repulsive force) is greater than the attractive force between the clay particles. Dispersion is seen as the cloudy appearance around the aggregates when left in water for some period.^[3] In the field, it can be seen as the cloudy and muddy appearance of water in puddles or in streams and rivers near construction sites or cultivated fields, after a rainstorm. Swelling of the clay domains is enhanced by the

presence of monovalent cations such as sodium (Na) and the presence of low electrolyte (salt) concentrations in the water or soil solution. Swelling is suppressed by the presence of divalent and trivalent cations^[7] and by the presence of high electrolyte (salt) concentrations.

CONSEQUENCES OF SLAKING AND DISPERSION

Slaking and dispersion are the fundamental processes of the degradation of structurally unstable soils, and most cultivated soils exhibit some degree of instability. These degradation processes can be associated with many soil physical problems observed in the field that affect plant growth or soil behavior.^[4,8] Waterlogging, reduced infiltration, crusting, hardsetting, compaction, poor timing of farming operations, and poor germination and establishment are generally perceived as distinctly different problems in the field, but as shown in Fig. 2, they have a common cause in slaking and dispersion and can therefore be corrected using the same treatment. Hence, an ameliorative treatment applied to reduce or prevent dispersion and to correct one particular problem will also correct many of the other physical problems. The most important effect of slaking and dispersion is the reduction of the soil's K associated with the blockage of pores between the larger particles or stable aggregates. A small increase in dispersion may result in large decreases in K.^[9,10]

FACTORS AFFECTING SUSCEPTIBILITY TO SLAKING AND DISPERSION

Since slaking and dispersion are associated with the swelling of clay domains and the inability of the forces of attraction or bonding to hold the clay domains together, they are affected by the nature of the clay minerals, the adsorbed cations, and the bonding mechanism.

Clay Type and Composition of Adsorbed Cations

Swelling clays (montmorillonites, vermiculites, and illites) tend to confer a degree of instability on soil aggregates, whereas non-swelling clays (kaolinites) are generally associated with high structural stability. Swelling is enhanced by the presence of Na and low electrolyte concentrations. Na-dominated clays continue to swell when the water content is increased and float apart in suspension,^[7] which is referred to as spontaneous dispersion. Swelling, slaking, and dispersion will also increase in response to the increasing proportion of Na or exchangeable sodium percentage (ESP). Although there is laboratory evidence for a threshold ESP,^[11] there is no clear evidence that a threshold ESP exists in field soils.^[4] However, for soil classification purposes, a soil is classified as sodic in Australia when the soil's ESP is equal to or greater than 6%^[6] and in the United

Fig. 2 A schematic diagram showing how slaking and dispersion may result in soil physical problems often observed in the field (shown in the rounded boxes) and plant growth.

Source: Adapted from So & Aylmore.^[4] ©1983.

States when the ESP is equal to or greater than 15%,^[10] indicating the increased probability of physical problems occurring on these soils when used for cropping. On the contrary, dispersion is reduced when the electrical

conductivity (EC) of the bulk solution increases. Therefore, a soil with a high ESP and high salinity may appear as well structured when dry but will immediately disperse following rainfall or when irrigated with low EC water.

Table 1 Strategies for managing slaking and dispersion.

Process	Aggregate hierarchical level affected	Action required	Management options available
Slaking	Macroaggregates	Prevent breakdown of bonds	1. Zero tillage or minimum tillage 2. Slow wetting during irrigation 3. Reduce droplet energy during spray irrigation
		Increase aggregate bonding and bonding strength	1. Incorporate organic matter 2. PVA application 3. PAM application 4. Lime or Ca carbonates application 5. Introduce grasses in crop rotation
Dispersion	Microaggregates and clay domains	Increase flocculation: 1. Replace monovalent cations with divalent or polyvalent cations (permanent exchangeable cation effect) 2. Increase electrolyte concentrations (temporary electrolyte effect)	1. Gypsum application 2. Lime application 3. Gypsum or slaked lime [Ca(OH) ₂] application

Calcium (Ca)-dominated clays exhibit limited swelling. Ca montmorillonite swells to a basal distance between two clays of 18 Å.^[12] At this distance, the electrostatic attractive forces between the clay plates are greater than the repulsive or swelling pressures between the plates. Ca- and magnesium (Mg)-dominated clays tend to flocculate, whereas Na-dominated clays tend to disperse. However, Mg clay does not have the same stability as Ca clay, and its tendency to disperse will depend on its combination with other factors, e.g., Mg clay will disperse following cultivation at much lower water contents than Ca clay.^[13] Soils with similar ESP tend to show greater dispersion when the other cation is Mg compared to Ca.^[14]

Trivalent cations such as Al³⁺ and Fe³⁺ confer the greatest stability onto clay domains. Hence, besides providing bonding materials to the aggregates, the presence of aluminum (Al) and iron (Fe) oxides and hydroxides ensures a large proportion of these cations being present in the diffuse double layer. Highly acidic soils (pH < 5) will have a high concentration of Al in solution, and these will stabilize the clay domains. Hence, Oxisols are generally non-dispersive soils and possess high structural stability.

Nature of Aggregate Bonding

Swelling and dispersion may be prevented if slaking of aggregates is prevented by strong bonds. The most common bonding materials for aggregates are in the order of abundance organic matter, Fe and Al oxides and hydroxides, Ca carbonates, and silica oxides. The strength of bonding increases with the amount present in the soil. The material that is readily affected by human activity is soil organic matter. In the virgin and undisturbed state, soils with high ESP are generally non-dispersive because of the

accumulated soil organic matter in the surface soil. However, cultivation reduces the soil organic matter contents, and when the bond strength from organic matter decreases below the swelling pressures from the sodic clay, dispersion occurs followed by the appearance of soil physical problems. Hence, the addition of adequate organic matter that will readily break down and produce suitable bonding material may prevent or reduce the dispersion of clay domains.

MANAGEMENT OF SLAKING AND DISPERSION

Managing slaking and dispersion of clay soils is the essence of managing soil structure. Table 1 lists a range of management options that have been used. Slaking can be managed at the macroaggregate level by avoiding the breakdown of existing bonds (organic matter) by minimizing soil disturbance (zero tillage) and/or through the addition of bonding material such as organic matter, polymers [such as polyvinyl alcohol (PVA) and polyacrylamide (PAM)], and Ca carbonates (lime). It can also be reduced by incorporating grasses into the existing crop rotation as grass roots, and associated fungal hyphae bind microaggregates to macroaggregates, besides maintaining or increasing soil organic matter contents.

On the other hand, dispersion can be managed at the microaggregate level by using a combination of divalent cations and high EC in the soil solution, e.g., the use of Ca ameliorants such as gypsum (CaSO₄ · 2H₂O) that provides Ca²⁺ and the continuous presence of adequate EC levels associated with its limited solubility (2.2 dS/m at 25°C). Gypsum is most useful on Na-dominated clays and other soils when dispersion occurs, e.g., following excessive cultivation. However, it may not be helpful on clays that are

already strongly dominated by Ca ions. Ca^{2+} replaces Na^+ from the clay exchange sites (exchangeable cation effect) that represent a permanent or residual effect of gypsum. The presence of a high electrolyte where free gypsum is present provides the dominant effect on sodic soils. It represents the temporary electrolyte effect of gypsum.^[4,9] Lime will provide a similar effect, but it is a slow-acting ameliorant.

CONCLUSION

The nature of soil structure is that it conveys specific properties to the soil, and any alteration such as the breakdown or structural development will affect the physical properties of the soil. The particles and aggregates of a soil are arranged in a hierarchical order where the lower orders tend to have higher densities and greater internal strength than the higher orders. Slaking (breakdown of the higher order: macroaggregates to microaggregates) and dispersion (breakdown of the lower order: microaggregates to particles) are the fundamental processes that are the cause of most of the soil physical problems encountered in the field that affects plant growth and soil behavior, such as waterlogging, reduced infiltration, crusting, hardsetting, compaction, poor timing of farming operations, and poor germination and establishment. Although generally perceived as distinctly different problems in the field, they can be corrected and managed using the same techniques, i.e., the prevention or suppression of the processes of slaking and dispersion in these soils.

Social and Behavioral Sciences' Contribution to Soil Science

Sven B. Lundstedt

School of Public Policy and Management, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

The social and behavioral sciences cover most of the ways to study human beings and their cultures and social systems. They are complex ways. Economics is considered by many to be both a social and a behavioral science. Since Keynes' time, economics has been basically divided traditionally into micro and macro levels of analysis. To the extent that soil science sees a need to connect some of its research questions to economic phenomena, it would be useful to study this important distinction.

INTRODUCTION

Inadequate soil management has led to wars of expansion and natural disasters that have, in turn, contributed to the very decline of nations and civilizations. We need but look to our human environment to see this important natural connection. The strong link between soil and human society is discussed further in the entries *Human Society and the Planet: Soil as a Heritage* (p. 1127) and *Human Society and Soil* (p. 1123).

OVERVIEW

Psychology has grown into an overwhelmingly complex, multifaceted discipline with many separate subdisciplines. If one is interested in human behavior and the individual's connection with soil phenomena, research questions might come in the form of new hypotheses about soil and individual people's various psychological and physical needs being met by soil reconstitution.

Sociology is traditionally a discipline that focuses on the social system (society) and all of its manifestations both large and small. Like other branches of science mentioned, it has many subdisciplines as well. Society has had a deep historical influence on the material substance called soil. The question of how social organizations treat the issues of soil management and development is important, especially whether sociological studies help or hinder agricultural problem solving. It is well to point out that sociology and agriculture have traditionally been partners.

Political science is yet another social and behavioral science that has focuses on political systems and governance. To the extent politics, e.g., plays an integral part in soil management, and soil issues have become exceptionally important. From federal to local and state government, agriculture has been working for it, a large and powerful political base in the U.S. society with many

powerful stakeholders and interest groups of varying kinds who participate in policy formation and implementation associated with fundamental soil issues.

Cultural anthropology has a distinguished research history of studying human cultures and subcultures of all kinds worldwide. That would include issues that bear upon soil considered in the light of all relevant facets of a culture. There is surely many human cultural aspects of the uses of soil which have been noted in anthropological studies of primitive and modern agricultural communities.

The concept of "latent policy," therefore, serves as a pivotal social psychological variable useful in explaining, quantitatively and qualitatively, the positive and negative public meaning of secretive policy behavior and its presence under circumstances where it is not customarily expected to exist or, even under law, should not exist.^[1,2]

A final example is one concerning the management of soil and, hence, soil policy as understood in the sense that is very much a part of agricultural policy formation. Policies governing the uses and the forms of management of soil exist in all societies in some form, although some are more advanced than others. Such policies are important because they reflect recognition of not only accumulated scientific knowledge of soil but also the agricultural policies (simply serving as rules) for best practices in its use in growing food, especially while being aware of the social structures and processes that are contexts for soil management practices.

Other societal processes and values play a part as well. Economic values and policies governing soil use practices, e.g., are surely among the most seriously affected by whether they are manifest, latent (transparent), or latent (secret) policies, which then often lead to transactional difficulties in bargaining and conflict management, especially in negotiations where transparency was initially intended but not, in fact, practiced. Lack of forthrightness and transparency suggests dishonesty in negotiation transactions and is a sure formula for failure in an economic transaction if true.

Yet “latent policy transactions” (secret deals) are in constant need of requiring careful application and scrutiny, even though the realists claim they are necessary facts of life and part of the cost of doing business. Those who look upon the inevitability will claim, cynically, for transactions to continue to exist among humans, and they will continue to exist as common attributes of the human uses of soil. Hence, as many insist, there is always some ongoing need for a control point and a certain amount of regulation. The Securities and Exchange Commission, e.g., stands out as an illustration of a public agency that seeks balance in such matters.

An illustration of another interdisciplinary approach is illustrated by Thompson and Mosely's high-Alpine tropical paleoclimatology research which provides examples of increasing global climate change. It suggests that a long-term crisis may arise from water reductions and drought from a decline in melting snow in the high Andes and African mountains such as Kilimanjaro, shrinking of both the Quelccaya Ice Cap, and the shrinking across the world in Africa of the Kilimanjaro ice fields. The social science of cultural anthropology has the methods to be more than quite capable of recording important social changes in communities affected by decreases in usable soil for agriculture.^[3-5] These underlying anthropomorphic changes can be important and are often poorly understood and blindly implemented, leading to serious human policy errors without further collateral validity.

LITERATURE AND SOME OF ITS POTENTIAL LESSONS ABOUT SOIL MANAGEMENT

It is appropriate to study the lessons provided by historic literature. Especially important is how such literature can often enlighten us about many important things, including the power of soil in all societies for both good and evil. John Steinbeck, author of *The Grapes of Wrath*, begins his novel writing about the enormous power of soil management gone wrong, thus triggering the social change and failed technology leading to the enormous human suffering associated with the Dust Bowl migrations of the 1930s in the United States.^[6]

In his first chapter, Steinbeck lays the “groundwork” for the striking human drama of a soil catastrophe with devastating social changes and human suffering to follow.

In the roads where the teams moved, where the wheels milled the ground and the hooves of the horses beat the ground, the dirt crust broke and the dust formed Men and women huddled in their houses, and they tied handkerchiefs over their noses when they went out, and wore goggles to protect their eyes When night came again it was black night, for the stars could not pierce the dust to get down, and the window lights could not even spread beyond

their own yards. Now the dust was evenly mixed with the air, an emulsion of dust and air. Houses were shut tight, and cloth wedged around doors and windows, but the dust came in so thinly that it could not be seen in the air, and settled like pollen on the chairs and tables, on the dishes. The people brushed it from their shoulders. Little lines of dust lay at the door sills.

Once that very dust was a nutrient-laden soil that sustained human agriculture and attacked hunger. With its disappearance came a crashing decline in one form of American agricultural subculture and rural civilization. Steinbeck alerted Americans to the grim reality of poor soil management and reminded many of the second-order economic and societal events such as the “Great Depression” that was coterminous with it.

Keeping this excerpt from Steinbeck's book in mind, recall that his book was published in 1939, a turning point of the “Great Depression.” The following citation, which contains excerpts from real situations reported by the *New York Times* on July 27, 2003, vividly illustrates some of the social conditions in Brazil which reflect soil management policies and promises that failed to be implemented. The setting is Mirante do Paranapanema, approximately 900 km South West of Rio de Janeiro.^[7]

The encampments have sprung up along highways throughout this fertile farming region and are expanding rapidly. Precarious clusters of shacks made of wood, cardboard and plastic, they are inhabited by thousands of peasants who have flocked here with a single unwavering demand: a piece of land.

In some cases, farms, cattle ranches and sugar mills have been occupied, threatening violent clashes. In other areas, squatters have in weeks seized or vandalized government offices, blocked highways, taken hostages and looted trucks to press their demands.

It almost came to this kind of response when the homeless farmers, retreating by necessity from soil erosion destruction, described so vividly and accurately by Steinbeck's novel, were forced west to California facing new difficulties over which they had little control at first. Fortunately, the suffering created by the initial real “dust bowl” experience about which Steinbeck wrote only lasted until World War II, which gradually introduced new resources and agricultural techniques to reverse it. The agricultural problems remained to be worked on long after World War II. However, the slave labor conditions for the “dust bowl” farmers created by a readiness of predatory efforts of some to exploit migrant human labor in California lasted only long enough to find new victims from Mexico and elsewhere south of the border. What were the social, monetary, and human costs of this initial western migration in order to escape from the toxic dust from used-up soils? Almost

incalculable amounts of money and pain, it would seem, when human suffering is considered!

This example of the power of soil for good and evil is the gist of a momentous social problem, essentially formed over soil rights, but it does not stop there; it reaches far beyond it to a human struggle for a new standard of living and quality of life. Perhaps, it is an unfortunate metaphor, but the circumstances can be attributed to the growth of a one-sided form of economic and social pathology in which the main symptoms are social chaos and even the danger of a revolution, rather than peaceful evolution. It is a widening of a dangerous conflict which is the result of not acting much earlier to intervene in peaceful ways, to act competently, and to take appropriate steps to solve this serious societal problem. There have been many warnings throughout the hemisphere in the last few decades, but only few were listened.

Many economists would argue that a robust market-oriented economy, with little governmental interference of course, is the only solution for these kinds of "sustainable development," and the sooner the better it would seem they would say. Yet for this solution to work, it had to happen much earlier in the 20th century, so that it could develop properly to include education. Equally as many other economists, perhaps, would prefer to see a larger government effort in the form of an aid plan using education and new forms of governance to guide the social change and its soil counterpart, it is so necessary for these problems to be solved equitably. According to some who have tired of the constant battles over resources and a workable structure, this intervention is, once again, too little and too late to do much else than to encourage the kind of violence described in this *New York Times* article.

For others, the only solution to these problems is found in using market forces to solve them and the less intervention the better, except, however, to increase trade in services, manufacturing, and agriculture and, of course, education, reflecting the need for trained workers. But if truth be admitted, the prognosis is unknown. In either case, it is an enormously complex situation in which only one or two social and behavioral sciences at work may not be enough, in addition to agricultural innovations and the soil sciences. The problems are not only political and economic. Soil science alone, while an essential science with a distinguished research history, cannot do the whole job.

INTERACTIVE ISSUES

A subject as broad as the social and behavior sciences can enlighten soil scientists by drawing their attention to these suggested intellectual bridge building.

There are several research issues that cross the boundaries of soil and social sciences. Research crossroads illustrate the involving partnerships, the hybrids, such as among these disciplines are growing, not diminishing. Hence, the rise of interdisciplinary "disciplines" involving the social and behavioral sciences and, say, soil science is increasing.^[3,6] One can even go a step further in to point out that many have reached into biology and physics to mention only two possibilities.

CONCLUSION

Social and behavioral sciences and soil science are truly evolutionary sciences. The interconnections formed by them may yet grow to have some additional future subject matter kinship with soil science, a most esteemed intellectual partner for the future. It is a question worth further consideration.

Sodic Soils

Pichu Rengasamy

*Department of Soil and Water Science, University of Adelaide, Waite,
South Australia, Australia*

Abstract

Soils with a high proportion of exchangeable sodium are considered sodic soils. On wetting these soils, clay particles swell and disperse degrading soil structure, and on further drying soils become dense. Poor water storage and restricted movement of air and water in soil profile lead to yield decline of many crops. Sodic subsoils cause accumulation of salts in the root zone. In dryland sodic soils, multiple problems such as salinity and toxic elements in addition to sodicity occur making management decisions difficult

INTRODUCTION

Sodic soils are those with a high proportion of sodium adsorbed to the soil particles compared to other cations such as calcium, magnesium, and potassium. Exchangeable sodium percentage (ESP) is a criterion used to identify sodic soils. When a soil with high ESP is wetted, the bonds between soil particles are weakened. As a result, the clay particles swell and often become detached and disperse at high water content. This leads to poor physical properties of soils. In the classification system developed in United States, a soil with an ESP > 15 is considered as “sodic,” and in Australia, the criterion is >6. These differences are owing to the influence of several soil factors including salt levels, pH, organic matter, and clay mineralogy on the adverse effects of ESP on soil properties. Sodic soils are widespread in arid and semiarid regions of the world extending up to 30% of the total land area (Table 1). Use of saline water, including waste and effluent waters containing sodium salts, for irrigation induces sodicity in soils. Sodicity is a latent problem in many salt-affected soils where deleterious effects on soil properties are evident only when salts are leached below a threshold level.^[1] While soil salinity reduces plant growth, directly affecting physiological functions through osmotic and toxicity effects on plants, sodicity causes deterioration of soil physical properties indirectly affecting plant growth and survival. Sodic soils are subjected to severe structural degradation and exhibit poor soil–water and soil–air relationships; these properties (Table 2) adversely affect root growth, thereby restricting plant production and making it difficult to work in soils when they are wet or dry.

YIELD DECLINE IN SODIC SOILS

Sodic soils make the paddocks prone to waterlogging, poor crop emergence and establishment, gully erosion, and in

some instances tunnel erosion. Because of the heterogeneity in the accumulation of sodium by soil particles, these symptoms may be observed only in certain parts of the paddock. Generally, patchy growth and barren patches are visible in a number of spots in a paddock, while the rest of the field may look normal. However, the effects of sodicity are fully realized in the harvested yield. The actual yield obtained in sodic soils is often less than half of the potential yield expected on the basis of climate, particularly rainfall and evapotranspiration.^[2,3] Relative yield of cereals grown in dryland sodic soils in Australia in relation to average root zone ESP is given in Fig. 1.

Swelling and dispersion of sodic aggregates destroy soil structure, reduce the porosity and permeability of soils, and increase the soil strength even at low suction (i.e., high water content). These adverse conditions restrict water storage and transport. Soils are, therefore, either too wet immediately after rain or too dry within a few days for optimal plant growth. Thus, the range of soil water content that does not limit plant growth and function (“non-limiting water range”) is very small.^[4] Dense, slowly permeable sodic subsoils reduce the supplies of water, oxygen, and nutrients needed for obtaining maximum potential yield. During the rainy season, even with prolonged ponding of water on the surface, only a small increase in water content occurs in subsoil. The low porosity leads to slow internal drainage and water redistribution within the profile.^[5] This reduction in water storage causes crop water stress during prolonged dry periods. Subsoil as a source of water and nutrients becomes more important in dryland cropping regions than in irrigated soils.

SALT ACCUMULATION IN ROOT ZONES OF SODIC SOILS

Soils with sodic subsoils are characterized by moderate to high exchangeable sodium and, in many cases, with high

pH (>8.5) where carbonate and bicarbonate minerals are present. Subsoil sodicity restricts drainage beyond the root zone and, as a result, salts accumulate in this zone. The concentration of accumulated salts fluctuates with rainfall pattern, input of salt from agronomic practices, and soil weathering, as schematically explained in Fig. 2. Dryland salinity or “seepage salinity” in many countries is associated with rising saline groundwater tables. However, the extent of subsoil salinity, also called “transient salinity,” not associated with saline groundwater is large in many landscapes dominated by subsoil sodicity. A relationship between rainfall, subsoil ESP, and EC_e for northeastern Australian soils has been reported.^[7] In dryland regions with annual rainfall between 250 and 600 mm, sodic subsoils have an EC_e between 2 and 20 that can dramatically

Table 2 Physical and chemical properties of a typical sodic soil profile in South Australia.

Properties	0–20 cm	20–40 cm	40–100 cm
Chemical properties			
pH _{1:5} (water)	7.9	8.9	9.2
EC _e (dS/m)	0.4	3.8	4.9
Organic carbon (%)	1.2	0.6	0.3
Exchangeable sodium (%)	6.2	14.6	24.5

Swelling (mm/mm)	0.04	0.18	0.20
Hydraulic conductivity at saturation (mm/day)	22.8	4.5	2.3
Penetrometer resistance at 100 kPa suction (MPa)	1.8	4.2	4.8
Aeration porosity (%)	9.7	4.8	3.9
Bulk density (Mg/m ³)	2.0	2.2	2.3
Final infiltration rate in the field (mm/hr)	0.2		

affect crop production through osmotic effects during dry periods. Laboratory-measured EC_e will increase several folds under field conditions as the soil layers dry in-between rainy days. The combination of poor water storage and osmotic stress enhances water stress to crops under dryland cropping.

ROOT ZONE CONSTRAINTS IN DRYLAND SODIC SOILS

Multiple problems occur in soils with subsoil sodicity. Soil compaction, crusting, and induration of subsoil layers require “physical” reclamation. Sodicity, salt accumulation, and alkaline pH require “chemical” reclamation.

Fig. 1 Relative yield of cereals grown in Australian sodic soils in relation to average root zone ESP.

Fig. 2 Salt accumulation in sodic subsoils.

All of these conditions cause, in addition to water stress, macro- and micronutrient deficiency, and toxicity owing to Na^+ , Cl^- , HCO_3^- , CO_3^{2-} , B, $\text{Al}(\text{OH})_4^-$, and others. Low organic matter and biological activity compound these problems encountered in sodic subsoils.

MANAGEMENT OF DRYLAND SODIC SOILS

Major criteria in increasing productivity in dryland sodic soil are improved water storage and transport in the root zone and crop water use efficiency. More information is available on agricultural management in sodic soils that is more relevant to irrigated lands.^[5] Reclamation procedures involving high costs are prohibitive in dryland regions because of low benefit/cost ratio.

Diagnosis of multiple problems with large variations, vertically and horizontally across the paddock, is primarily important. Gypsum is the most commonly used compound to reclaim sodic soils. Subsoil reclamation may involve higher rates of gypsum application or deep placement of gypsum by deep ripping or deep plowing. Salt-tolerant plant species may alleviate subsoil salinity. Plants that can tolerate ion toxicity such as boron, carbonate, sodium, and chloride have also been identified. Strategies to improve subsoil fertility may include: 1) mechanical means of placing nutrients deeper in the profile; 2) using nutrient sources of lower or higher mobility; 3) using deep-rooted legumes to fix nitrogen at depths; and 4) selection of plant species

and genotypes better suited to acquiring nutrients from subsoils. Research is needed on developing plants that modify the rhizosphere and adapt to edaphic conditions. Farming systems should be developed to prevent accumulation of salts and toxic elements in the root zone of sodic soils.

CONCLUSION

Soils with a high proportion of exchangeable sodium are considered sodic soils. On wetting these soils, clay particles swell and disperse degrading soil structure, and on further drying soils become dense. Poor water storage and restricted movement of air and water in soil profile lead to yield decline of many crops. Sodic subsoils cause accumulation of salts in the rootzone. In dryland sodic soils, multiple problems such as salinity and toxic elements in addition to sodicity occur making management decisions difficult. Soil amelioration with gypsum and choice of tolerant crops are useful in farming these soils.

Sodic Soils: Formation and Global Distribution

Brian Murphy

New South Wales Department of Land and Water Conservation, Cowra, New South Wales, Australia

Abstract

Sodic soils, which are considered a subset of salt-affected soils, have levels of exchangeable sodium that are sufficiently high enough to cause swelling and clay dispersion in water having low electrolyte concentrations, such as under rainfall and in many irrigation waters. These properties cause serious environmental and productivity problems.

INTRODUCTION

A functional definition of a sodic soil is as follows:

Whenever exchangeable sodium is present in sufficient concentrations to influence soil behaviour, sodicity occurs, a soil is said to be sodic.^[1]

Precise problems depend on where sodicity is in profile. Typical problems associated with sodic soils include:^[2,3]

- dense impermeable subsoils causing waterlogging and restricting root growth;
- surface crusting and sealing restricting emergence and surface infiltration, hardsetting seedbeds;
- development of a toxic chemical environment for root growth;
- high susceptibility to erosion, especially deep gully erosion (Fig. 1);
- contamination of surface waters by sediments and colloid-assisted contaminants; and
- instability in engineering structures; piping or tunneling can occur in structures associated with these soils.^[3]

ASSESSMENT AND RECOGNITION

The occurrence of any of the above problems is often sufficient to indicate at least the possibility that soils are sodic. From a classification viewpoint, sodic soils are traditionally considered to have dense impermeable subsoils with a coarse columnar to prismatic structure. Surface soils are often of a lighter texture than the subsoil and may be bleached in the lower layer (A2 or E horizon) (Fig. 2). These soils are identified in the Food and Agriculture Organization of the United Nations/United Nations Educational, Scientific and Cultural Organization, Russian, Canadian, and old Australian schemes by the terms solonetz or soloth.^[4,5] In *Soil Taxonomy*, this group of soils relates to the natric Alfisols. In a new Australian soil classification,

the order sodosol is used to identify soils with sodic properties.^[6] However, soils with sodic layers are common in many other soil types, especially the Vertisols and Aridisols of *Soil Taxonomy*^[7] and the Vertosols of the Australian Soil Classification System.^[6]

The level of exchangeable sodium percentage (ESP), which is the amount of exchangeable sodium as a percentage of the total cation exchange capacity of the soil, is used to confirm the identification of sodic soils. ESP is used as this gives a strong indication of the actual and potential dispersion behavior of the soil. Two of the most commonly used critical levels of ESP are 15% for U.S. soils^[8,9] and 6% for Australian soils.^[1,6,10] The level of ESP that begins to adversely affect the soil behavior can vary with the level of soluble salts in the soil, the nature of soil clays, soluble minerals present in the soil, and other factors. Sumner^[11] presented a more detailed history of the definition of sodic soils and the development of critical values of ESP.

As dispersion is the most critical property that causes the limitations of these soils, measures of dispersion have been used to identify sodic soils. Dispersion can be measured by aggregate tests or suspension tests.^[1] Spontaneous dispersion of soil aggregates in water is usually a strong indication of the presence of a sodic soil. However, the accuracy of dispersion tests to predict the presence of sodic soils is influenced by the level of electrolyte concentration as described in Fig. 3, with the critical level of ESP that causes dispersion being dependent on the electrical conductivity of the soil solution. As a general rule, classification systems have adopted the convention that the levels of ESP used to identify sodic soils are those that predict the dispersion behavior of the soil in water with a low electrolyte concentration (rainwater or freshwater).^[11]

Sodic and Saline Soils

The close association between saline and sodic soils has led to some confusion when discussing these soils. Sodic

Fig. 1 Severe gully erosion in sodic subsoils formed on granite parent material.

soils are salt-affected soils but are not necessarily saline. Sodicty relates to the level of exchangeable sodium in the soil with the positive charge of the sodium ion being balanced by the negative charge on the clay minerals and organic matter. Soils may be sodic without being saline. Salinity relates to the level of free salt present in the soil solution. In saline soils, the positive change of the soluble cations, such as sodium ions, is balanced by anions such as chloride, sulfate, or bicarbonate present in the soil solution.

In general usage, the following soils have come to be recognized:^[1,11]

1. Sodic and saline soils with a high ESP (>15% in the United States and >6% in Australia) and high soluble salts ($EC_{sat} > 4$ dS/m), where EC_{sat} is the electrical conductivity of the saturation extract.
2. Sodic and non-saline soil with a high ESP (>15% in the United States and >6% in Australia) and low soluble salts ($EC_{sat} < 4$ dS/m).

Fig. 2 Example of a typical profile of a sodic soil profile—solonetzic soil or soloth-sodosol-natric xeralf.

ORIGIN AND FORMATION

Sodium, which on average is 2.64% of the atoms in the earth's crust,^[13] is highly mobile on the landscape and tends to become the dominant cation as solutions move further from their original source. This has a significant effect on the origins and the formation of sodic soils. Ultimately, the only condition for the formation of sodic soils is that sodium becomes accumulated on the clay exchange complex. Therefore, there are numerous mechanisms for the formation of sodic soils.

Traditionally, sodic soils are thought to develop by the following pathways as described by Bui et al.:^[4]

1. Initial salinization of the soil from saline parent material or rising saline groundwater.
2. Leaching of salts and dispersion and downward movement of clays (illuviation) to form an abrupt texture change at the top of the B horizon.

The link to saline and arid areas for sodic soils is evident.

Fig. 3 Schematic diagram of effect of ESP, sodium adsorption ratio, and EC levels on dispersion in sodic soils.
Source: Adapted from Rengasamy, Greene, et al.^[12]

Subsequent work has shown that this apparently simple process can, when combined with weathering and the pedological, geomorphological, and chemical processes occurring on the landscape, lead to a number of pathways for the development of sodic soils.^[4,14]

The Formation of Sodic Soils

A brief summary of the possible pathways for the formation of sodic soils is given below and is summarized in Fig. 4. At any location, more than one pathway for the formation of sodic soils can be operating.

Fig. 4 Schematic diagram summarizing the origins and development of sodic soils.

Geological—long-term development of sodic soils

1. Weathering of rocks with high levels of sodium relative to calcium and magnesium can release sodium, especially from sodic plagioclases and alkali feldspars, and lead to the development of sodic soils associated with these rocks.^[4]
2. Aeolian sources of salt and therefore sodium cations are a major source in many areas.^[14] Ocean is the main source of aeolian salt in some areas, but aeolian salt blown from arid terrestrial sources is highly significant for many areas of sodic soils.
3. The erosion and deposition of sodic clays is another possible pathway for sodic soils to develop on the landscape. Sodic clays are especially susceptible to water erosion, and the erosion and deposition may result in the formation of sodic clays in areas of deposition. Saline sodic clays may be susceptible to wind erosion because of aggregation associated with their salinity.
4. The buildup of sodium and salt in association with marine incursions of the sea in the Quaternary or Tertiary periods.^[5,14]

Short-term development of sodic soils associated with human activities

1. Rising groundwater with high salinity can lead to salinization of the soil and the development of sodic soils.
2. Irrigation with water with high sodium levels relative to calcium and magnesium can lead to the development of sodic soils.

GLOBAL DISTRIBUTION OF SODIC SOILS

Sodic soils are widespread throughout the world, many of them occurring in important agricultural areas. Most of them occur in drier areas but significant amounts also occur in more humid areas. The total area of sodic soils is estimated by Lubbock^[15] to be more than 550 million hectares. Szabolcs^[16] estimated that 932 million hectares was affected by salinity/sodicity worldwide, of which 581 million hectares was sodic soils. Although there are difficulties in estimating such figures because of varying criteria for identifying sodic soils and the lack of specific on-the-ground data, this estimate does give an indication of the potential problem of sodic soils as a world environmental and productivity issue. Sodic soils occur on all the continents, but the largest areas are in the driest continent, Australia.

The broad distribution of sodic soils on a global basis is given in Table 1.^[4]

Table 1 Summary of the global distribution of sodic soils.

Continent	Estimated area (million hectares)
North America	9.6
South America	57.9
Africa	27.1
Europe	22.9
Northern and Central Asia	120.1
Southern Asia	1.8
Australasia	340

CONCLUSION

Sodic soils are a major group of problem soils. They are potentially productive if managed properly, but can be severely degraded or can cause severe environmental problems if managed inappropriately. It is likely that increasing salinization worldwide will increase the areas of these soils. Therefore, knowledge about the origins, formation, distribution, and management of these soils is seen as a valuable input to managing scarce and vulnerable natural resources.

Sodic Soils: Humid Regions

Samuel J. Indorante

U.S. Department of Agriculture—Natural Resources Conservation Service
(USDA-NRCS), Du Quoin, Illinois, U.S.A.

Abstract

Sodium-affected soils (SASs) usually occur in arid, semiarid, and subhumid climates. To a much lesser extent, SAS can occur in humid regions with a mean annual precipitation (MAP) > 100 cm. SAS genesis in humid regions is similar to SAS genesis in more arid regions and varies with the climate, parent material, topography, vegetation or land use, and length of the time taken for sodium (Na) soil genesis. The SAS genesis model tends to follow the sequence of salinization, desalinization, solonization, and solodization. Taxonomical and land management classification of SASs is based on soil morphology and chemical properties. Accurately identifying and mapping SAS is the first step in managing these areas to overcome the production problems caused by the high Na concentration and poor physical makeup of SAS.

BACKGROUND INFORMATION

Sodium-affected soils (SASs) or sodium (Na) soils are soils that have been adversely affected by Na salts and/or exchangeable Na. They usually occur in arid, semiarid, and subhumid climates where rainfall is insufficient to leach soluble salts from the soils, or where internal drainage is restricted. To a much lesser extent, SAS can occur in humid regions (Table 1) with a mean annual precipitation (MAP) > 100 cm because of factors that restrict leaching of soluble salts from the soil. The main factors are a source of Na, high water table, clayey dense subsoils, impermeable underlying geologic strata, and seasonal periods of high evapotranspiration.

SASs in humid areas tend to be leached of excess salts, but they contain enough exchangeable Na to disperse the clay particles. The presence of exchangeable Na, as measured by exchangeable sodium percentage (ESP), under low salt conditions, as measured by electrical conductivity of the saturation extract (ECe), causes the breakdown (peptization or dispersion) of soil aggregates (Fig. 1).^[1] These high ESP, low ECe soils tend to be sticky when wet, and highly erodible, and have poor tilth, low porosities, low infiltration rates, and low permeabilities.

Soil moisture recharge in these SAS profiles is slow, and these soils also dry slowly. When these soils dry up, they become hard, cloddy, and crusty (Fig. 2); when wet, they are sticky and difficult to work. The adverse effect of exchangeable Na on soil structure and associated soil–water and soil–plant relationships makes crop production difficult even in humid climates (MAP > 100 cm).

GENESIS OF SAS IN HUMID AREAS

SASs can occur over a wide range of climates, but generally under highly, seasonally contrasted ones of arid to

humid conditions.^[2,3] The rate and degree of SAS genesis vary in each of the climates and also vary with parent materials, topography, vegetation or land use, and the length of time Na soil genesis has taken place. There are several main environmental factors that promote the genesis of SAS in all climates: the presence of shallow saline groundwater or a saline soil solution; textural discontinuities during the deposition of eolian, glacial, alluvial, or colluvial sediments; occurrence of perched water tables within 1 m of the surface; low-slope gradients; and impeded drainage.^[2] These environmental factors in a given climate control water movement over, into, and through the soil profile and the soil landscape. Water movement, in turn, controls the distribution of soluble Na salts and exchangeable Na in Na soil profiles and across the soil landscape.^[4,5]

SAS genesis pathways have been described in arid climates,^[2] semiarid climates,^[3,6] subhumid climates,^[3,5] and humid climates.^[7–10] The sequence of pedogenic processes tends to follow but is not restricted to the classic sodic soil genesis model as summarized by Miller and Pawluk.^[11]

Sodic Soil Genesis Model

Salinization—this first step begins with salt accumulation because of Na-rich parent material or capillary rise of shallow saline groundwater. The periodic alternation of dry and humid conditions is necessary, with high rates of evapotranspiration in the summer.

Desalinization—this step begins with the leaching of salts by water moving through the soil profile.

Solonization—this step begins with the leaching of salt by rainwater, which leads to the dispersion of clay if ESP exceeds 10–15% and total soluble salt content is 0.1–1.5% or less, and the formation of a sodic soil. The translocation

Table 1 Global distribution (km²) of SAS with humid soil moisture regimes.

of dispersed clays will eventually lead to an abrupt textural change between A and B horizons.

Solodization—the final step is Na-induced hydrolysis and eluviation at the top of the slowly permeable B horizon.

The sources of Na in humid climate SAS include Na-bearing minerals in medium-textured Loess,^[9] coarse-textured Loess,^[10] alluvial deposits,^[12] and fluvial terraces.^[7] Humid climate SASs are formed under both forest^[7] and mixed forest prairie and prairie vegetation^[9] and occur on level^[9,10,12] and gently sloping^[7,9] landscapes.

NOMENCLATURE AND CLASSIFICATION OF SAS

SASs are primarily classified in terms of soil morphology, including soil texture, soil structure, and the presence of a

Fig. 1 Schematic diagram illustrating clay behavior as a function of ESP and ECe.
Source: From Kamphorst & Bolt.^[1]

Fig. 2 A SAS spot intermingled with non-SASs in southern Illinois, U.S.A. The climate is humid.

diagnostic horizon. They are also classified in terms of chemical properties including pH, ECe, electrical conductivity of the 1:5 soil to solution ratio (EC_{1:5}), ESP, and sodium adsorption ratio (SAR). The specific criterion used to define and classify sodic soils varies by geographic region and the goal of the classification system. Taxonomical classifications are designed to serve the multiple purposes of soil survey.^[13] Land management classifications group soils for SAS for the purpose of site-specific management of Na soil areas for agronomic and related uses.

Taxonomical Classification

One of the most common taxonomical characteristics for classifying Na soils in all climates is the presence of a natric horizon. This term is defined as a mineral soil horizon that satisfies the requirements of an argillic horizon but also has prismatic, columnar, or blocky structure and a subhorizon having an ESP >15%.^[13,14] The Australian soil classification system^[15] uses the presence of a sodic horizon to define its Sodosols (SAS). The Australian sodic horizon is a clear or abrupt textural B horizon that is sodic (ESP > 6) in all or part of the B horizon, depending on the thickness of the horizon and a pH > 5.5. Some taxonomical classifications of SASs in humid regions are Natraqualfs, Natrudalfs, Natralbolls, Natraquolls, Natraquerts, and natrudolls;^[13] others are hydromorphical solonetztes,^[16] solodic sodosol,^[15] and gleyic and mollic solonetz.^[14]

Land Management Classification of SAS

Common terms used to label, describe, and classify SAS in humid regions for management purposes are as follows:

- Sodic—a non-saline soil containing sufficient exchangeable Na to adversely affect crop production and soil structure under most conditions of plant growth. The SAR of the saturation extract is >13.^[17]

- Sodic non-saline—soils that have an SAR of the 1:5 soil to soil solution ration ($SAR_{1:5}$) between about 3 and 10 but insufficient salt to maintain the clay in a flocculated condition.^[18]
- Very sodic non-saline—Soils having an $SAR_{1:5} > 10$ and very low $EC_{1:5}$ values, which would be highly dispersive and have poor physical properties.^[18]
- Non-saline-alkali—soils for which the ESP is >15 and the ECE is <4 mmhos/cm. The pH usually ranges between 8.5 and 10.^[19]
- Solonetz (in humid regions)—soils that are leached of excess salts and have a well-developed structural B horizon with ESPs from 5% to 20%.^[3]

IDENTIFYING, MAPPING, AND MANAGING HUMID SAS

SASs have primarily been identified and mapped using traditional soil survey methods, which include aerial photo interpretation, the application of local soil-landscape models, soil sampling with the associated field tests, and laboratory analysis. Even when mapping at large scales (1:12,000 to 1:31,680), SASs are often mapped as complexes of SAS–non-SASs because of the irregular shape, relatively small size, and the intricate geographic mix of SAS–non-SASs. Along with the traditional soil survey methods, geophysical techniques, such as electromagnetic induction, have been applied successfully in the identification and detailed mapping of SAS in humid regions^[20,21] and subhumid regions^[22] for both taxonomical classification and land management classification.

Once the SAS have been identified, mapped, and classified, the next step is the management of these areas for specific crops or land uses. An example of the importance of site-specific management and reclamation of SAS for crop production can be seen in a comparison between corn (*Zea mays* L.) and soybean [*Glycine max* (L.) Mer.] yields in SAS and corresponding non-SAS in the humid Midwestern United States.^[23] The two soils are cisne (fine, montmorillonitic, mesic vertic albaqualfs) and huey (fine-silty, mixed, mesic typic natraqualfs)^[13] and are typically mapped as a complex. Under the same climate and management factors, and under non-irrigated conditions, the huey soils (with more than 15% ESP in the subsoil) had an average 18% yield reduction for soybean and an average 38% yield reduction for corn when compared with the cisne soils.

Applications of gypsum ($CaSO_4 \cdot H_2O$), done in conjunction with water table management and tillage, are likely to produce the most success in the reclamation of SAS in humid areas for crop production. These cultural practices should help prevent soil swelling and dispersion; increase porosity, structural stability, hydraulic properties, soil tilth, drainage, and leaching; and reduce dry soil strength.^[24]

CONCLUSION

The adverse effect of exchangeable Na on soil structure and associated soil–water and soil–plant relationships make crop production difficult, even in humid climates. Crop production in these areas provides a unique challenge and opportunity for soil scientists and crop scientists. Through a better understanding of humid region SAS systems, scientists may find better ways to manage these areas to overcome the production problems caused by the high Na concentration and poor physical makeup of SAS.

Sodic Soils: Irrigation Farming

David Burrow

Agriculture Victoria, Tatura, Victoria, Australia

Abstract

The area of irrigated soils affected by sodicity is expanding with increasing use of saline–sodic groundwaters and wastewaters. Infiltration and movement of irrigation water through soil are impeded with high exchangeable sodium (Na) percentage and low soil salinity. The accumulation of high Na concentrations in the soil also interferes with calcium and nitrogen uptake in crops. Consequently, management of irrigation water quality with respect to SAR_{iw} and EC_{iw} is critical for soil management. Minimum tillage and the use of cover crops, mulches, gypsum, and dissolved organic polymers in irrigation waters aim to stabilize surface soil aggregates in sodic soils. The modulation of irrigation frequency and volumes can improve crop water availability and leaching of sodic salts from the profile. Slow-wetting irrigation methods reduce the breakdown of surface aggregates. The provision of surface and subsurface drainage is essential for many sodic soils to prevent waterlogging and the accumulation of salts in the root zone. Advances in computer simulation software can improve the management of sodic soils under saline–sodic irrigation.

INTRODUCTION

Sodic soils, which occur naturally in many of the arid and semiarid regions of the world, exhibit poor chemical and physical properties. Soil management and farm operations are often difficult on these soils. Furthermore, farmers are frequently encouraged to use poorer quality saline–sodic wastewaters and groundwaters for irrigation, either alone or blended with surface waters, and this is leading to increased land area affected by sodicity. With increased use of saline–sodic irrigation water and its application to many soil types, farmers and scientists need to better understand the processes underpinning the management of sodic soils for the maintenance or improvement of crop productivity.

PROPERTIES OF SODIC SOILS AFFECTING IRRIGATION FARMING

Hydraulic Properties

The movement of water into the soil following rainfall or surface irrigation, its redistribution within subsurface layers, and its drainage below the root zone are important for productive irrigation farming. Water entry into the soil, measured by the infiltration rate (IR), and through soil layers, measured by the hydraulic conductivity (HC), both decrease with increasing exchangeable sodium (Na) and decreasing soil salinity. For strongly sodic soils, heavy rainfall or low-salinity irrigation may lead to surface waterlogging on flat land or run off on sloping ground.^[1] Similarly, freshwater irrigation of

sodic soils with low HC may lead to shallow depths of wetting, uneven wetting, and low water capacity in plants.^[2] These hydraulic traits, together with lower air-filled porosity and excessive penetration resistance in dry soils, can restrict plant growth.^[3]

The low IR of a strongly sodic soil during irrigation is usually attributed to the formation of a surface seal or crust, which in turn derives from the physiochemical dispersion of clay-sized particles from unstable surface aggregates. These dispersed clay particles migrate with water flow and eventually block conducting pores.

Early studies showed that soil HC varies up to two orders of magnitude, depending on the salt concentration of a percolating solution and soil-exchangeable Na percentage.^[4] Reductions in HC were explained by swelling and dispersion of clay particles, but these factors are modulated by clay mineralogy, sesquioxide and calcium carbonate content, soil texture, organic matter content, pH, soil weathering, and other exchangeable cations.

The effects of soil sodicity on IR and HC, resulting from saline–sodic irrigation, are exacerbated in climatic zones with a marked rainfall season because of the leaching of salts from surface soil horizons. Rainfall with negligible salinity ($EC < 0.1$ dS/m) infiltrates and reduces soil EC below a threshold electrolyte concentration (TEC) in these layers, resulting in clay swelling or dispersion. In the field, these processes are not necessarily detrimental to HC as they may be accommodated by pore geometry and slow wetting rates or circumvented by preferential flow through large cracks. However, the maintenance of soil EC above TEC is an essential first step toward managing sodic soils under irrigation.

Nutrient Status

In sodic soils, high Na to calcium (Ca) and magnesium (Mg) to Ca ratios reduce the amount of Ca available for plant uptake and can induce Ca deficiencies in crops. Data, obtained principally from greenhouse and laboratory studies, indicate that cereal species are sensitive to Ca deficiencies and particularly during seedling growth stages.^[5]

Poor productivity on sodic soils has also been attributed to lowered availability and plant uptake of nitrogen or micronutrients. Nitrogen availability in these soils is restricted under anaerobic conditions,^[6] while micronutrient availability is controlled by adsorption and precipitation reactions.^[7]

The relative solubility of boron (B) and high Na/Ca ratios in some sodic soils also means that B and Na toxicity may contribute to crop production losses. However, the relative importance of nutrient availability and specific ion toxicity on crop production losses for sodic soils is difficult to judge because of the compounding influence of poor soil physical properties on crop growth and yield.

SOIL MANAGEMENT

Specific tillage operations and cropping systems have been designed to overcome some of the poor physical properties of sodic soils.^[1,8] Field grading and raised-bed cropping systems are used in landscapes of low gradient to encourage runoff and limit surface waterlogging. Deep ripping is used to break up massive subsoil structures and for the incorporation of gypsum into subsurface horizons. Shallow tillage, at moisture contents close to the lower plastic limit, is used to generate seedbeds of fine tilth, rather than massive clods. Following crop establishment, zero tillage is typically advocated to minimize mechanical destruction of surface aggregates and subsequent dispersion of clays during irrigation.

Tillage practices, which aim to stabilize surface soil aggregates of an appropriate size distribution, are aided by the use of cover crops, mulch applications, and gypsum applications.^[11] Soil cover crops, such as *Lolium rigidum*,

tend to stabilize topsoil aggregates by means of entwining root systems and the incorporation of root mucilages within the root zone. Mulches are used for the creation of a more favorable soil microclimate that encourages turnover in microbial populations, microbial detritus, and the generation of stabilizing, organic glues. Careful applications of gypsum or other Ca products at the soil surface aim to reduce soil sodicity or maintain soil EC above TEC.

IRRIGATION MANAGEMENT

Water Quality

Water quality guidelines for crop production based on salinity (EC_{iw}) and sodicity (SAR_{iw}) have been developed for infiltration, crop salinity tolerance, and specific ion toxicity.^[8] In contrast, water quality guidelines for soil permeability (HC) and potential dispersion of clay tend to be based on soil chemical properties.

According to infiltration guidelines, calculated on paired EC_{iw} and SAR_{iw} ranges, the quality of irrigation waters used throughout the world (Table 1) should rarely limit their application to land.^[8] However, when the EC of infiltrating water falls below 0.2 dS/m, e.g., as occurs after rainfall, severe infiltration problems are predicted. Crop salinity tolerance guidelines predict severe Na toxicity for sensitive crops, based on $SAR_{iw} > 9$, and severe salinity effects on crop productivity, based on $EC_{iw} > 3$ dS/m. However, these predictions when applied to data in Table 1 only concern irrigation of crops with drainage waters because of their typically high SAR_{iw} and EC_{iw} .

The use of an adjusted SAR_{iw} ($adj\ R_{Na\ iw}$) in Table 1 accounts for the effects of high bicarbonate concentrations in some irrigation waters. Bicarbonate tends to precipitate Ca, and to a lesser extent Mg, as a carbonate solid, with the net result of an increase in SAR_{iw} . The transformations of Ca (and Mg) between soluble, exchangeable, and precipitated forms are modulated by pH and the partial pressure of CO_2 , hence these two factors indirectly affect SAR_{iw} .

Table 1 Mean and range of values for EC_{iw} , SAR_{iw} , and $adj\ R_{Na\ iw}$ of irrigation sources throughout the world.

Irrigation Practices

Specific irrigation practices complement tillage and chemical additions to improve the production potential of sodic soils. These practices include increased frequency of irrigation, preplanting irrigation, and adoption of alternative irrigation systems. Uniform applications of polyacrylamide or finely powdered gypsum to topsoils, for the purpose of stabilizing fragile aggregates, are also best achieved through an initial irrigation.

Increasing the frequency of short-duration irrigations on soils with high initial IR (e.g., cracking clays) and low final IR (due to sodicity) maximizes the periods of high IR to wet the root zone and minimizes the risk of waterlogging. Preplanting irrigation wets the entire rooting depth and if timed correctly allows restoration of soil aeration before crop planting. This technique is especially effective on sodic soils of very low IR. A change from surface irrigation systems (e.g., flood or furrow) to sprinklers or drippers can alleviate waterlogging on low IR soils by matching water delivery rates to the IR. The slow wetting of topsoils also decreases aggregate slaking and clay dispersion under these systems of alternative irrigation.

DRAINAGE OF SODIC SOILS

Drainage is essential for the continued practice of irrigation farming on sodic soils. Surface drainage prevents waterlogging and the development of anaerobic conditions in the topsoil, while adequate subsurface drainage allows leaching of toxic or plant-dehydrating salts from the profile.

For some irrigated regions, the presence of a shallow watertable restricts drainage through a diminished hydraulic gradient. These watertables are frequently saline-sodic and contribute to sodification of soils via capillary transmission of Na salts. Hence, the removal in these regions of subsurface water through drains (open or piped) and pumped bores is essential for Na management. Because the installation of open or piped drains is expensive, the use of cheaper mole drains within subsurface layers has been proposed. However, in unstable sodic soils, mole drains collapse soon and therefore are not generally used.^[9]

Periodic leaching of soil profiles is required for removal of salt or toxic ions. Analytical equations have been developed to predict the leaching requirement for soil sodicity under saline-sodic irrigation.^[10] However, these equations do not fully account for Na-induced changes in IR or HC, which impinge on leaching capability.

Practically, intermittent irrigation is more efficient in salt removal than continuous ponding by promoting diffusion of salts into more favorable leaching pathways. Efficient leaching of sodic soils also requires irrigation with water of low SAR_{iw} and EC_{iw} > TEC in addition to the provision of subsurface drainage for removal of salts.

CONCLUSION

A range of farm management practices on irrigated sodic soils have been briefly described. Adequate control of water quality with respect to SAR_{iw} and EC_{iw} and the provision of drainage to remove excess sodic salts from the root zone are pivotal in controlling soil sodicity. Concurrent management of surface soils with ameliorants (e.g., gypsum, organic polymers, and mulches), cover crops, and appropriate irrigation methods enhances farm operations on these sodic soils at relatively low cost. Adequate modification of drainage and sodicity in subsoils is more costly and therefore less frequently attempted, particularly for cereal and forage crops. Consequently, the control of soil sodicity in irrigated farming remains focused on irrigation water quality, irrigation systems and scheduling, provision of surface runoff, and application of soil ameliorants to the soil surface. The continual emergence of irrigation and soil chemistry simulation software for computers should enhance further scientific research and refine farm management of soil sodicity.

Sodic Soils: Physical Properties and Behavior

Hwat Bing So

School of Agriculture and Food Sciences, University of Queensland, St. Lucia, Queensland, Australia

Abstract

The physical properties and behavior of sodic soils are determined not only by the level of exchangeable sodium percentage (ESP) but also by its interaction with the soil solution concentrations generally measured as the electrical conductivity (EC). The principal effect of high ESP is swelling of the clay fraction following wetting, which is exacerbated by low EC and will result in slaking and dispersion and the subsequent blockage of pores. The soils hydraulic and mechanical properties will be adversely affected by these processes, which may be followed by other observable problems in the field such as waterlogging, crusting, and/or hard setting.

INTRODUCTION

When the exchangeable sodium (ES) in the soil is present in sufficient quantities to influence its behavior, the soil is considered to be sodic (see also the entry *Sodic Soils: Formation and Global Distribution*, p. 2032). Exceptions are the sub-plastic soils, which may remain stable and unaffected by high levels of ES.^[1] Although the effect of sodium (Na) on soil behavior increases progressively with the level of ES percentage (ESP) in the laboratory, soils in the field are classified using the concept of a critical level of ESP, wherein soil properties or behavior is likely to be adversely affected by the high ESP level. The most widely used critical levels are an ESP of 15% for U.S. soils^[2] and 6% for Australian soils.^[3] The difference between the two was due to the electrical conductivity (EC) of the water used for testing the soil, during the development of these critical levels.^[4] The original level of ESP >15% selected by workers in the U.S. Salinity Laboratory, California, U.S.A., as the threshold above which the soil structure was adversely affected was based on hydraulic conductivity (HC) measurements using tap water having a threshold electrolyte concentration (TEC) of 3–10 mmol L⁻¹ (EC 0.4–1.3 dSm⁻¹), while that TEC used in Australia was 0.7 mmol L⁻¹ (EC 0.09 dSm⁻¹).^[1] As a result, a much higher ESP was required before degradation was initiated in the California study.

These differences highlight the importance of soil solution concentrations in the manifestation of the effect of ESP on soil behavior. Furthermore, the Australian opinion was based on the analysis of many clay soils, whereas the U.S. opinion was based on the analysis of soils with textures lighter than sandy loam.^[1]

EFFECT OF SODICITY ON SWELLING AND DISPERSION OF CLAYS

In homoionic clay systems, Na-clay swells considerably more than calcium (Ca) clay (Fig. 1), and swelling in

Na-clay increases rapidly as the electrolyte concentration decreases^[5] until clay particles become detached from each other when the electrolyte concentrations become very low and produce spontaneous dispersion of the clay particles.

In normal soils, the clay fraction is associated with a range of cations, which are generally dominated by Ca and magnesium with a smaller complement of Na and potassium (K) ions, and aluminum ions in acid soils with a pH less than 5.5. The principal effect of high sodicity on soils is the swelling of clay fraction following wetting associated with the hydration of Na ions, which leads to slaking of the aggregates and dispersion of the clay size fraction, which consists of clay particles and aggregates <2 microns. The dispersed material is effective in the blockage of pores, leading to a reduction in pore sizes, which in turn affects the hydrologic and mechanical properties and behavior of the soil (see the entry *Slaking, Dispersion, and Crust Formation*, p. 2021). The severity of the effect of dispersion is partly dependent on the clay content of the soil. At lower clay contents (<30%), the soil matrix is sandy with inherently large transmission pores and high HCs. In contrast, soils with higher clay contents (>30%) have a clayey matrix, and the number of transmission pores is determined by the degree of structural development. The same degree of dispersion tends to have a greater effect on soils with a clayey matrix when compared with a soil with a sandy matrix.

The effect of increasing Na on the amount of dispersed clay in Vertisols is shown in Fig. 2.^[6,7] Although it is common to express Na content as ESP and the amount of dispersed clay as dispersion ratio of clay, a better relationship was obtained for dispersible clay (DC) and ES contents, both expressed as a proportion of the bulk soil

$$DC = 0.029 + 0.023(ES); R^2 = 0.77^{***} \quad (1)$$

Furthermore, the inclusion of clay content improves the relationship further, indicating the separate effect of texture on the amount of dispersed material

Fig. 1 Swelling of Na and Ca montmorillonite clay, as a function of solution content and water potential expressed as pF.

Source: Adapted from Aylmore & Quirk.^[5]

$$DC = -0.021 + 0.013(ES) + 0.0012(\%Clay); \quad (2)$$

$$R^2 = 0.88^{***}$$

EFFECT OF SODICITY ON THE HYDROLOGIC PROPERTIES AND BEHAVIOR OF SOILS

The soils HC (K) is strongly and negatively correlated to DC content ($R^2 = 0.56^{**}$). Therefore, excessive Na in the soil affects K through its effect on clay dispersion and the

subsequent blockage of pores. K is strongly correlated with ES ($R^2 = 0.44^{**}$) as shown in Fig. 3.^[7] ESP has also been shown to be strongly and negatively correlated with K, independent of clay content and type.^[1]

Critical levels of Na in the soil are rarely shown in the laboratory; however, field assessment of degradation associated with Na is generally based on whether there are detrimental effects on the soil's productivity, which is principally affected by the amount of plant available soil water (ASW) over a crop growth season. ASW is the difference between water input, controlled by the soil infiltration rate, and the water output from the root zone,

Fig. 2 DC content as a function of ES content on two Vertisols from Queensland, Australia. Solid circles are the Waco soil (clay content 70%) and open circles are the Langlands soil (clay content 54%).

Fig. 3 Soil HC (K) as a function of ES content for two Vertisols from Queensland, Australia.

Source: Adapted from So & Aylmore.^[8]

controlled by the drainage rate, and both rates are affected by the soil HC. As K decreases, the soil infiltration and drainage rates also decrease. Initially, they may slow down the recharge of the soil water storage but remain adequate for the requirement of the plants. However, at the critical ESP, the reduction in K becomes sufficiently large to reduce the amount of water storage such that crop growth becomes affected. On this basis, the critical ESP will vary with the prevailing seasonal rainfall, but this relationship has yet to be quantified. The most common critical level of sodicity used to indicate the probability of such reduction is ESP of 15% in the United States (11) and 6% in Australia.^[3]

A reduction in the rate of drainage in sodic soils will increase the probability of surface waterlogging following rainfall or irrigation, which may significantly reduce germination and establishment of seedlings.

EFFECT OF SODICITY ON THE MECHANICAL PROPERTIES AND BEHAVIOR OF SOILS

Surface waterlogging would reduce soil strength and its ability to support mechanical loads and hence a reduced trafficability. It increases the time when the soil is in a plastic state and not suitable for tillage; therefore, its workability is reduced. On drying, the surface seal forms a crust or a hard setting surface depending on the texture and structural status of the soil. Clayey soils are dominated by highly active clay particles, which interact and form aggregates. The larger the aggregates, the larger are the transmission pores between them and the higher is the HC. However, the presence of excessive Na combined with rapid wetting will result in slaking and dispersion of the immediate surface aggregates, which leads to a

surface seal and a hard surface crust when dry. The higher the ESP, the harder is the crust formed as shown in Fig. 4.^[8] The thickness of the crust depends on the size of the dry aggregates,^[8] while the size of the crust depends on the rate of drying, being larger when the rate of drying is slower. The development of surface crusting leads to a reduction of evaporation and consequently a subsoil below the crust that remains wet for longer periods. When subjected to traffic under such conditions, the load transmitted to this wet subsoil will lead to compaction, while cultivation leads to cloddy surface conditions.

In contrast, fine sandy or silty soils are dominated by particles that are sufficiently large to have very low or no surface activity and, therefore, tend to remain as individual particles. On the other hand, they are small enough to block transmission pores. Therefore, soils with a high content of fine sand and silt in the surface horizon are inherently unstable. Their aggregates readily slake and disperse throughout this horizon when wet. Under wet conditions, these soils are very soft and highly susceptible to deformation and compaction. Because of the low water holding capacity associated with the predominance of coarse particles, these soils rapidly dry into a hard setting soil and are sometimes referred to locally as a “Sunday soil,” being too wet for cultivation on the Saturday and too dry on the Monday. As conditions suitable for cultivation are restricted, sodic soils tend to give rise to cloddy seedbeds. Cultivation when it is too wet will compress the soils into large clods, while cultivation when it is too dry and the tensile strength of soil is high will also result in cloddy seedbeds. Both conditions will require additional cultivation and energy to create a suitable seedbed.

High ESP is associated with a lower liquid and plastic limit and would require more energy to cultivate (see the entry *Slaking, Dispersion, and Crust Formation*, p. 2021) and lead to the perception of a soil with a heavier texture than that indicated by its particle size distribution. The use of gypsum to ameliorate the effect high ESP has on clay soils increases the ease of tillage due to a reduction in soil strength.^[9]

CONCLUSION

The presence of high amounts of Na (high ESP) in the soil gives rise to a variety of physical and mechanical problems in the field through its effect on swelling, slaking, and dispersion.

Sodic Soils: Processes, Characteristics, and Classification

Pichu Rengasamy

Department of Soil and Water Science, University of Adelaide, Waite, South Australia, Australia

Abstract

Land managers with paddocks that are prone to waterlogging, poor crop or pasture emergence, gully erosion, or tunnel erosion may be experiencing the effects of sodicity. Sodic soils are formed by the adsorption of Na^+ by the negatively charged sites on soil particles, particularly soil clays from soil solutions containing free sodium (Na) salts such as sodium chloride, sodium carbonate, sodium bicarbonate, and sodium sulfate. The soils are considered to be sodic when the free salts are leached from the soil layers and only exchangeable Na remains adsorbed on soil particles. If free salts are also present, the soils become saline-sodic. Sodic soils are generally found in arid and semiarid regions with high evapotranspiration and low rainfall associated with low leaching that are responsible for salt accumulation.

CHARACTERISTICS OF SODIC SOILS

The negative charge, which depends on the type and amount of clay materials, plays a vital role in the adsorption of Na. Negative charge in soils increases with the content of clay minerals in the order smectites > illites > kaolinites. Soils dominant in positive-charged sites such as Oxisols containing oxides of aluminum and iron, and low pH soils generally have negligible amounts of exchangeable Na. Soils with pH-dependent charge minerals increase their negative charge with increasing pH. The more the negative charge, the more is the adsorption of Na in soils.

Although soil sodicity is a result of chemical reaction (cation exchange) with the salts, it mainly affects soil physical properties and thus plant growth and productivity. It is possible that the release of high amounts of Na^+ in soil solutions can be toxic, which are encountered in saline-sodic soils. Sodic soils have an extremely poor physical condition (Table 1), leading to an inadequate balance between water and air regimes within the soil. The imbalance stems from restricted water acceptance and transmission properties, which result in the soil being too wet or dry for much of the time, and leads to poor root development and crop growth. In addition, sodic soils are difficult to cultivate and have poor load-bearing characteristics. The lack of structural stability in these soils promotes soil hardening throughout soil profile and seal and crust formation at the soil surface, resulting in soil erosion and pollution of water bodies.^[1–3] Poor drainage in sodic soils also causes secondary salinity in subsoil layers.^[4]

SOIL PROCESSES

Swelling and dispersion of clay particles on wetting are the major processes responsible for the deterioration of physical behavior of sodic soils. In saline-sodic soils with high electrolyte concentration, swelling is minimal and clay dispersion is absent. Both swelling and dispersion behavior are governed by the balance between attractive and repulsive forces, arising from intermolecular and electrostatic interactions between solution and the solid phases in the soil. The distinction between saline and sodic soils arises because these forces vary, depending on whether the soil solution is concentrated (saline) or diluted with a high proportion of Na to divalent ions in the solid exchange phase to cause swelling and dispersion (sodic).

Soil scientists have used models based on pure clay minerals involving Lifshitz-van der Waals, ion correlation, hydration, and electrical diffuse double layer forces generated between colloidal particles suspended in water to explain sodic soil behavior.^[5] But soil clay systems that are complex, heterogeneous intergrowths of different clay structures intimately associated with organic and biopolymers do not behave in the same way as their pure clay mineral counterparts. Thus, classical theories of colloidal behavior such as Derjaguin-Landau-Verwey-Overbeek (DLVO) theory^[6] may not satisfactorily explain the behavior of sodic soils.

The processes that occur during the initial wetting of dry aggregates, resulting in swelling to the final stage of aggregate disintegration and leading to dispersion of soil clays when completely wet, are important in understanding

Table 1 Example of properties of sodic soils compared to an ideal soil that is highly productive.

Properties	Sodic soil	Ideal soil
PH _{1:5} (water)	9.2	6.0–8.0
Electrical conductivity (EC) _{1:5} (dS/m)	0.2	<0.4

sodic soil behavior. The polar nature of water molecules and solvation reactions with the solid phase is primary factors in causing swelling and dispersion. Clay particles in dry soil aggregates are bound together by inorganic and organic compounds involving several types of bonding, which produce strong, attractive pressures of the magnitude of megapascals.^[8] The water stability of an aggregate depends on the strength and persistence of these linkages in the presence of water molecules, which, in turn, are functions of the type of bonding. Bond strength in the presence of water generally decreases in the order: covalent, hydrophobic, Lifshitz-van der Waals, coordination complexing, hydrogen, and finally ionic bonds. In contrast to covalent bonds, ionic bonds are readily solvated by water molecules. Similar to pure Na compounds, Na–clay linkage is easily solvated and ionic bond is broken, whereas calcium and magnesium ions are linked to clay particles by polar covalent (combination of covalent and ionic) bonds, with decreased ionicity compared to Na linkage. The degree of covalency in a bond involving metal cations depends on ionization and ionic potentials.^[3] The tendency to form covalent bonding increases in the order: Na⁺, K⁺, Mg²⁺, Ca²⁺, Fe³⁺, and Al³⁺, for example. Thus, both the type of cation and the nature of clay ligand determine the ionicity of the clay–cation–clay bonds.

Highly ionic bonding in sodic clays leads to extensive hydration and swelling with increasing water content, and finally, with separation of linkages on water saturation, clay particles disperse spontaneously in water, whereas in calcium, or magnesium-saturated clays with polar covalent bonding, limited hydration leads to limited swelling without any separation (or dispersion) of clay particles. Only on mechanical agitation, these clays can disperse. The flocculation of dispersed clay particles is brought about by the addition of electrolyte, which as a result of

its osmotic effect causes dehydration of clay water system, thereby bringing clay particles together. Therefore, saline–sodic soils do not have severe deterioration of physical properties. The order of flocculating power is Ca²⁺ > Mg²⁺ > K⁺ > Na⁺. Thus, gypsum, a calcium compound, is very effective in reclaiming sodic soils. In addition to its flocculating effect, gypsum also promotes removal of Na from clays by way of cation (calcium) exchange.

CLASSIFICATION

There is a need for a uniform system of classification of salt-affected soils that distinguishes between saline and sodic conditions and is useful for soil management. The international nomenclature^[9] includes the terms “sodic,” “alkali,” “solonchak,” “solonetz,” and “solodized solonetz,” and the complex interrelationship between them makes comparison between sodic soils difficult. The classification of saline and sodic soils devised by the U.S. Department of Agriculture widely followed in many countries is as follows:

Saline, non-sodic soils – Exchangeable sodium percentage < 15

EC in saturation paste (ECe) > 4dS/m

Sodic, non-saline – ESP > 15 and ECe > 4dS/m

Non-saline, non-sodic – ESP < 5 and ECe < 4dS/m

The effects of exchangeable Na on soil physical behavior vary from soil to soil and are influenced by several factors such as electrolyte concentration, pH, organic matter, biopolymers, and aggregate stability in water. Therefore, the definitions used on the basis of ESP vary according to practical experience. The following classes have been proposed^[10] on the basis of physical behavior of sodic soils:

Class 1: Dispersive soils. Soils that disperse spontaneously without shaking will have severe problems associated with crusting, reduced porosity, etc. even when subjected to minimum mechanical stress, e.g., under zero tillage.

Class 2: Potentially dispersive soils. Soils that require inputs of mechanical energy (raindrop impact and tillage) to bring about dispersion will experience soil physical problems when mechanically disturbed.

Class 3: Flocculated soils. Soils that contain more than the minimum electrolyte concentration required for flocculation of clays (or prevention of dispersion of clays) will present few physical problems, but salts could be excessive and limit productivity.

Measurements of clay dispersion along with ESP or SAR, EC, and pH will be necessary for managing saline and sodic soils. Based on these principles, a detailed proposal^[11] on

classification of salt-affected soils is available, but this has to be tested for practical applications.

CONCLUSION

Although soil sodicity is a result of chemical exchange reactions of the accumulated Na salts, it mainly affects soil physical properties and thus plant growth and productivity. The physico-chemical processes involved in sodic soils are briefly described. The classification of sodic soils on the basis of soil characteristics and dispersion/flocculation behavior is also discussed.

Sodic Soils: Reclamation

Jock Churchman

Land and Water, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Adelaide, South Australia, Australia

Abstract

Two main mechanisms are involved in the reclamation of sodic soils: 1) improvement in water flow; and 2) displacement of exchangeable sodium ions.

IMPROVEMENT IN WATER FLOW

Sodic soils show a low permeability to water. Their permeability can be improved quite rapidly by increasing electrolyte concentrations^[1,2] (the “electrolyte effect”). Ions in solution tend to inhibit the swelling and dispersion of fine clay particles by compressing the electric double layers of adjacent particles (Fig. 1). The volume around the particle surfaces within which repulsion takes place is reduced, ultimately to zero.

It has been found^[2] that there is no swelling and dispersion when the total electrolyte concentration exceeds a critical level, i.e., the “threshold electrolyte concentration” that depends on soil properties.^[1,4]

DISPLACEMENT OF EXCHANGEABLE SODIUM (NA) IONS

The deleterious effects of exchangeable Na reflect the more extensive hydration of the Na ion than that of other common exchangeable cations on soil particles (Fig. 2). Exchangeable Na, which forms an ionic association with the clay surface, causes hydration, dissociation of particles, and hence swelling and dispersion.^[5] By contrast, exchangeable calcium (Ca) forms polar covalent bonds with the clay surface.^[5] Ca shows only limited hydration and dissociation of particles and therefore causes only limited dispersion and swelling.^[5] Na⁺ on exchange sites is replaced by Ca²⁺ for the longer-term remediation of sodic soils.

CHEMICAL AMELIORANTS

Gypsum

Soluble sources of Ca ions are the most suitable sodic soil ameliorants. While gypsum is used most often, not all sources of gypsum are similarly effective or similarly suitable for each specific problem from sodicity. It was found^[1,6] that only “by-product” gypsum, as a surface

application, could prevent crusting. Mined gypsum was too slowly soluble for the purpose.^[1] Gypsum is a by-product of many industrial processes.^[6] Furthermore, gypsums from different mines can differ quite markedly in purity.^[7] They can also differ in dissolution rate. A finer particle size generally provides a greater solubility.^[6] As well, Na salts associated with gypsum (Table 1)^[7] decrease its efficiency for amelioration.^[8]

Lime

Lime has also been used as an ameliorant for sodic soils.^[7,9,10] While generally less soluble than gypsum, lime may provide a useful incidental source of Ca ions when used to raise the pH of acid sodic soils. It may provide a cheaper alternative to gypsum or else be used in association with gypsum to extend the lifetime of the Ca reserves.^[7] Because of its increased solubility in the presence of Na salts, it may be more effective than gypsum for the reclamation of saline sodic soils. Lime also contributes less to the salt load than gypsum.^[10]

Reclamation of Calcareous Sodic Soils

Calcareous sodic soils have an abundance of Ca, but it is present as calcium carbonate (CaCO₃) and hence is insoluble at the high pH of these soils. Their sodicity is often overcome through acid additions,^[11,12] either directly or indirectly. Additions of elemental sulfur, pyrite, iron and aluminum sulfates^[11,13] and also organic matter^[14] provide acid through microbial activity for indirect acidification. Plant growth can also help dissolve native CaCO₃.^[13]

Miscellaneous Chemical Ameliorants

Sodic soils may be reclaimed with soluble sources of Ca that include waste materials, e.g., acidic cottage cheese whey,^[1] acid resin by-products of the oil industry, and also CaCl₂ as an industrial by-product.^[4] Addition of polymers can also increase the permeability of soils.^[1]

Source: From van Olphen.^[3]

ROLE OF BIOLOGY AND ORGANIC MATTER

Effects of Plant Growth

Rice culture ameliorates sodic soils through the build-up of carbon dioxide and hence dissolution of CaCO_3 , among other effects.^[11] Among crops, rice is particularly tolerant

to sodicity, and some grasses are also highly tolerant^[11,13] (Table 2).

Ameliorants are readily leached out of soils, so losing the benefit of the electrolyte effect. In addition, Na^+ from Na salts often present in soils can replace exchangeable Ca^{2+} . Therefore, long-term reclamation probably requires increased plant growth and hence enhanced biological activity^[14] and stabilization of soil structure. This occurs partly through transient binding agents, e.g., roots, hyphae, polysaccharides, and hydrophobic binding,^[14] and partly through associations between soil organic matter and Ca^{2+} in the soil system. Organic matter has a stronger affinity for Ca than for Na,^[14] so it is most effective when used with gypsum or lime to help restore a stable structure to soils.^[14] There is a resulting increase in stable pores for the transmission of water and nutrients, root growth, and soil stability.

Effects of Additions of Organic Matter

Due to its stabilizing effect on soil structure, organic matter can also help to reclaim sodic soils when added to soils, even though additions of organic matter can sometimes also enhance their dispersion, with resulting physical problems.^[14] The different effects vary with types of soils and also of organic matter.^[14] The addition of readily decomposable organic matter tends to reduce the pH of calcareous sodic soils and hence to aid their reclamation.^[14]

STRATEGIES FOR THE RECLAMATION OF SODIC SOILS

Reclamation without the Addition of Ameliorants

Reclamation can be achieved slowly without ameliorants by many cycles of irrigation and cropping.^[11] As well,

underlying calcareous or gypsiferous layers may be incorporated into upper parts of the soil profile through deep plowing.^[4]

Optimal Supply of Ameliorants

The effectiveness of gypsum can be increased by its placement in cracks for their stabilization so that they remain open to conduct water, air, and plant nutrients when soils become wet.^[1] Water flow to subsoil layers, aeration, and hence higher crop yields were achieved by incorporating gypsum in narrow tilled slots.^[13] More generally, gypsum is often incorporated into subsoil layers by tillage.

Ameliorants may also be used in association with other additions. Only a little gypsum applied with acidifying nitrogenous fertilizers led to effective reclamation of a saline-sodic soil.^[1] This combination confers immediate benefits through a higher electrolyte concentration and also medium-term benefits through an increased supply of exchangeable Ca ions. Enhanced plant growth from fertilizer use provides long-term benefits.

Supply of Water for Reclamation

Ameliorants are only effective when dissolved. A supply of water and its flow through the profile are required for effective amelioration. Irrigation and/or rainfall may supply water, but the quality of water available for irrigation can vary. Gypsum can be supplied in electrolyte-free irrigation water, as in parts of California.^[13] Saline-sodic irrigation water, including water commonly derived from groundwater sources, may exacerbate the deleterious effects of sodicity when its application during the dry season is followed by rains, as can occur in Israel.^[13] In this case, (by-product) gypsum is applied to the surface prior to the rainy season.^[13] Adequate drainage to beyond the root zone should accompany irrigation in order to

leach displaced electrolyte, but this should not cause increased salinity in underlying groundwater.^[12]

As long as there is provision for the disposal of the salt water, dilution with salt water^[3,12] is also useful in sodic soil reclamation. Its immediate effect is to increase the hydraulic conductivity of sodic soils by the electrolyte effect, but long-term reclamation will occur provided it also contains sufficient Ca (Ca : total cations ≥ 0.3). This can be added as gypsum.

Rate of Supply of Ameliorants

All additives increase costs, so their optimal use is required. The cost of transporting gypsum often limits application rates. Recommendations from field trial results of the most effective application rates for ameliorants are necessarily specific to soil type and climate, among other factors. Nonetheless, both simulations^[9,15,16] and laboratory studies^[17] have shown that the solubility of gypsum increases as the proportion of exchangeable Na on the soil increases. They have also shown that gypsum is more effective when mixed throughout the soil than when applied to the soil surface alone. Simulations^[10] have shown that reclamation is primarily limited to the depth interval in which gypsum was applied (Fig. 3A). They have also shown (Fig. 3B) that the electrical conductivity (EC) of the solution within and below the gypsum-amended layer decreases as the exchangeable sodium percentage (ESP) within that layer decreases.

Nonetheless, calculations of gypsum requirements have been based on 1) the exchange of Na by Ca, rather than the attainment of a sufficiently high electrolyte concentration EC to maintain a low permeability, and 2) assumptions of chemical equilibrium. The gypsum requirements for the achievement of a suitable permeability by the electrolyte effect also depend on the inherent EC

Fig. 3 Computer-model results (ESP and EC) for reclamation of a soil (initial ESP = 50; CEC = 200 mmol_c kg⁻¹) with gypsum and water (EC = 0). Numbers next to each line are depths of applied water.

Source: From Oster & Frenkel.^[10]

of the soil solution.^[12] Because mineral dissolution can maintain a high EC throughout most of the soil profile, gypsum often needs to be added to the soil surface only, mainly to prevent crusting. Assumptions of equilibrium, while strictly invalid, have probably been useful for the calculation of gypsum requirements because of low flow rates of percolating solutions and high surface areas of gypsum particles.^[11] Models of soil and water flow, e.g., UNSATCHEM,^[17] which consider equilibrium and kinetic expressions for ion exchange and the dissolution and precipitation of minerals and also ameliorants, may enable more robust calculations of requirements for ameliorants.

Ultimately, the main purpose of reclaiming sodic soils is to obtain the maximum possible improvement of yield of the particular crop in relation to the cost of ameliorant applied. Work in the Australian sugar industry^[18] has established a quantitative relationship between percentage increase in ESP and consequent loss in sugarcane yield. Sugarcane yield decreased by 1.5–2.1 tonne ha⁻¹ for every 1% increase in ESP.^[18] This relationship forms the basis of a cost–benefit analysis for calculating gypsum application rates from the ESP, the quality of the gypsum used, the quality of irrigation water, and economic factors. These include the cost of gypsum and its application, the price for the product (sugarcane), and the discount rate.^[19] Clearly there are opportunities for more practical calculations of this kind to be carried out for other crops and in other soil and climatic environments.

Sodicity: Subsoil

Kwong Yin Chan

Organic Wastes Recycling Unit, New South Wales Department of Primary Industries, Richmond, New South Wales, Australia

Abstract

Subsoil sodicity refers to the problems associated with the presence of excessive concentration of exchangeable sodium in the subsoil. Many soils with subsoil sodicity are characterized by low hydraulic properties and plant available water capacity, salinity, alkalinity, and deficiencies of micronutrients and toxic ions.

Large areas in different parts of the world with subsoil sodicity are marginal land with low productivity. However, based on available information, to what extent the low productivity is directly related to subsoil sodicity is not clear. Critical limits and criteria commonly used to assess sodicity of surface soils are not necessarily applicable to the subsoils. The ameliorative techniques are reviewed and further research needs are discussed.

INTRODUCTION

Subsoil sodicity refers to the problems associated with the presence of excessive concentration of exchangeable sodium (Na) in the subsoil. The latter is the layer below the plow layer, i.e., the Ap horizon or its equivalent in the undisturbed soil profile. In the literature, most of the information on sodicity has been derived from surface soils and often the distinction between surface and subsoil sodicity is not made clear. For example, sodic soils are defined as soils with exchangeable sodium percentage (ESP) exceeding 6% in any part of the top meter of the soil profile.^[1] Using the critical ESP value of 6% or 15% as criterion, sodic subsoils are widespread in many parts of Australia, Indo-Gangetic Plains in India, parts of Canada, and the United States.^[2] However, critical limits and criteria commonly used assessing sodicity of surface soils^[1–3] are not necessarily applicable to subsoils.

CHARACTERISTICS AND EFFECTS ON SOIL FUNCTIONS

Many soils with subsoil sodicity are characterized by the following properties, some of which are not directly/indirectly results of high concentration of exchangeable Na:

Low Hydraulic Properties and Plant Available Water Capacity (PAWC)

Many soils with high concentration of exchangeable Na subsoils have impeded infiltration and drainage as well as low plant available water.^[2,3] In surface soils, the poor physical conditions of sodic soils are caused by the processes of swelling and dispersion of clay particles originally bound in

the structural units (aggregates and peds) occurring at the surface.^[4,5] In contrast, low permeability of sodic subsoil is largely attributed to clay swelling rather than dispersion in the subsoil environment. As a result, it is now well recognized that methodology and results of sodicity effects relevant to surface soils are not applicable to subsoils.^[3] A “throttle” with very low hydraulic conductivity was identified in the 25–50 cm of a duplex soil with sodic subsoil using field measurements.^[6] The impeded hydraulic property of the subsoil layer restricts soil water storage from rainfall under dryland conditions. A negative relationship between PWAC and ESP at 0.6 m depth was established for soils in Queensland, Australia^[3]

$$\text{PWAC} = 13.671 e^{-0.0191\text{ESP}}$$
$$r^2 = 0.72 \text{ (for ESP} > 1.5 \text{)}$$

Salinity

In many sodic soils, both ESP and salinity increase with depth. Hence, many sodic subsoils are also saline.^[2,3] A linear relationship was established between saturated electrical conductivity at 0.9 m depth and ESP for soils with annual rainfall between 280 and 2200 mm yr⁻¹ in Australia.^[3] Therefore, soils with high sodicity are likely to be saline in their subsoils, particularly in the lower rainfall areas and for those soils with clay content of about 40–50%, corresponding to the transition from a coarse to a fine matrix.^[3]

Alkalinity

Some sodic subsoil soils have high pH (~10) due to the presence of carbonates and bicarbonates of Na.^[2] The high

pH conditions can result in nutritional troubles in crops^[7] and exacerbate soil structural problems.^[2]

Deficiencies of Micronutrients and Ion Toxicity

Nutritional constraints to plant growth have been identified in some sodic subsoils and include deficiency in micronutrients such as zinc, iron, and manganese, especially in the alkaline sodic soils as well as ion toxicity such as boron and molybdenum.^[7] Availability of micronutrients in alkaline sodic soils is not well understood.

CONSTRAINTS TO CROP PRODUCTION

Large areas in different parts of the world with subsoil sodicity are marginal land with low productivity.^[2,3] However, as many of these soils also have high ESP in the surface layer, it is not clear to what extent the low productivity is directly related to subsoil sodicity. The sodicity vs. yield relationship derived for surface soil^[8] is unlikely to be applicable to subsoils. Furthermore, regression analyses suggest that while large yield responses are obtained by reducing ESP of the surface soil (0–10 cm), they are not significantly affected by variation in the subsoil ESP.^[8] While low productivity of these soils might, to some extent, be related to adverse soil properties such as low PAWC, high bulk density, and low hydraulic conductivity,^[2,3] all of which are caused by the high ESP (sodicity) and the consequent subsoil stability, other properties are often, but not

always, associated with sodic subsoils, namely high salinity, pH, and toxic ions, can also result in poor plant growth and production. For instance, boron toxicity is the major factor-limiting crop yield in some soils with subsoil sodicity.^[7] Subsoil salinity can have opposite effects on crop growth and production. While directly limiting the available water to plant due to osmotic effect of the soil solution on the one hand, it can also help to counteract the adverse effect of sodicity by reducing clay swelling.^[3]

ENVIRONMENTAL IMPACTS

Tunnel erosion leading to gullying in many parts of the world is commonly associated with sodic B horizon.^[2] In Australia, many soils with sodic subsoils are duplex, namely soil profiles with large texture contrast between the A and B horizons. Gullies are formed by dispersion and washing away of the sodic B at points of water entry such as rabbit burrows followed by collapse of the overlying A horizon. The same process can lead to piping and tunneling in earthworks and dam walls.^[9] These gullies, failed earthworks, and dam walls are sources of sediments and water contaminants.

AMELIORATION AND MANAGEMENT

Methods being used to ameliorate subsoil sodicity have been reviewed.^[9,10] They fall into the categories presented in Table 1.

Table 1 The ameliorative methods for overcoming subsoil sodicity.

Methods	Description of technology	Advantages	Limitations
Gypsum application	Surface application of gypsum	Specialized machinery not required, positive responses have been reported for some soil types	Effects on reducing subsoil sodicity occur very slowly
Deep tillage/gypsum	Deep ripping of soil to depth with incorporation of gypsum	Quick responses, using readily available machinery	Uneven mixing of gypsum, large amounts of soil disturbance, variable and even negative responses, improvements often short term due to recompaction, excessive leaching of nutrients
Gypsum slotting	The soil is disturbed to depth only in narrow vertical bands (100–150 mm wide and spaced 1–2 m apart), which are filled with loosened soil mixed with gypsum at rates required to overcome sodicity	Large yield responses and soil improvements have been documented	Costly, special slotting machine needed, significant loss of macroporosity due to lateral swelling has been noted
Cropping strategies	Use of strong-rooted crops in rotation systems such as safflower (<i>Carthamus tinctorius</i>) to loosen subsoil biologically, use of raised beds, more frequency irrigation	Low cost, does not require large disturbance of soil profile, suitable for Vertisols	Subsoil sodicity not removed
Breeding of tolerant species	Breeding of species that are tolerant of sodicity and/or other associated problems, i.e., salinity, boron toxicity	Does not require large disturbance to soil profiles and use of non-renewable resources, large yield responses possible	Long-term research needed, sodicity problems remain

Choice of ameliorative methods is often governed by economics. Expensive methods such as gypsum slotting can only be considered for intensive agricultural enterprises. So far, effects of deep tillage on sodic subsoils have been variable, negative responses have been reported due to rapid recompaction, exposure of subsoil problems such as salt, and toxic minerals. For sodic soils with high ESP throughout the profiles, it might be more cost-effective to first address the problem of surface sodicity. Biological ameliorative methods, e.g., using deep-rooted plants and tolerant species, might be better long-term strategies for improving the productivity and sustainability of these soils.

RESEARCH NEEDS

Critical limits and criteria used for assessing sodicity of surface soils are not applicable to subsoils. More research on quantifying the effect of subsoil sodicity on soil functions and crop productivity is needed. More effective ameliorative and management of these soils require better understanding of the other constraints, e.g., salinity and B toxicity, which are often but not invariably associated with sodicity. These can be achieved by providing more detailed mapping and soil classification with clearer information on the location of subsoil sodicity in the soil profile and better identification of other associated limiting properties.

Soil Carbon Map: Africa

Arwyn Jones

Roland Hiederer

Luca Montanarella

European Commission, Joint Research Centre, Institute for Environment and Sustainability, Ispra, Italy

Abstract

The soils of Africa hold an important soil organic carbon (SOC) pool that is distributed very inhomogeneously over the continent. Values range from very low or negligible levels in the deserts of the Sahara, the Kalahari, and the Horn of Africa to very high in the wetlands of Sudan (Sudd), Democratic Republic of Congo (Ngiri–Tumba–Maingombe), Congo (Sangha–Nouabale–Ndoki), Rwanda, Burundi, Tanzania, and the Barotse Floodplain in Zambia. The soils of the tropical zone contain slightly more carbon (C) than the soils of the savannah regions. From the amended version of the Harmonized World Soil Database, soil C stocks for continental Africa have been calculated as 80.1 Gt C for the layers of 0–30 cm and 74.5 Gt C for the depth of 30–100 cm (this gives a total of 154.6 Gt C for 0–100 cm depth). The soils of the Democratic Republic of Congo and Sudan hold the most SOC with 19.11 and 12.65 Gt, respectively. Various estimates place the total terrestrial C pool of Africa (this includes aboveground vegetation and also all SOC, not just that in the upper 1 m) at between 250 and 280 Gt. In this context, soil holds between 55% and 70% of the total African terrestrial C pool. It should be noted that data for African SOC pools and sinks are quite imprecise and that the uncertainties associated with these values can be very large. Significant additional effort and investment are required to improve these estimates and spatial resolution of the soil biophysical properties in order to better quantify the impact of human activities on the SOC reservoir of Africa.

INTRODUCTION

The Biological Carbon (C) Cycle

One of the most important functions of soil is its role in the terrestrial C cycle by facilitating the conversion of atmospheric carbon dioxide (CO₂) to living matter and then its breakdown and release to the environment. Biology plays an important role in the movement of C between soil and atmosphere. Through photosynthesis, green plants use solar energy and water to turn atmospheric CO₂ into carbohydrates (i.e., sugars, starch, and cellulose), the principle compounds that are necessary to buildup biomass for plants or the bodies of animals. Most C leaves the biosphere through respiration and the decomposition of organic matter (C₆H₁₂O₆, e.g., litter fall and roots). Where oxygen (O₂) is present, aerobic respiration occurs, which frees the energy contained in the sugars and transforms carbohydrate “fuel” back into CO₂, which is released back to the atmosphere as follows:

When O₂ is lacking, e.g., in soil that is saturated with water due to poor drainage, then microbial communities

(e.g., *Methanobacterium*, *Methanosaeta*, and *Methanosarcina*) catalyze the breakdown of organic matter anaerobically. In these conditions, organic matter is broken down to produce methane (CH₄) and CO₂:

The amount of C entering the terrestrial C cycle by photosynthesis and released back into the atmosphere by respiration each year is about 1000 times greater than the amount of C that moves through the geological cycle on an annual basis. CO₂ and CH₄ are important greenhouse gases that affect the earth's climate. This makes soil an important component in the study of climate change.

Soil Organic Matter and C

Organic matter is often described as the “life force” of the soil. It creates pores in the soil that help the roots of plants to develop and store significant amounts of water, thus increasing the soil's capacity to withstand drought conditions. Organic matter can attract the ions of essential nutrients and, as a result, reduce the risk of valuable plant food being leached away. The same process can

Fig. 1 A profile of a Phaeozem from Tanzania—a soil that develops under natural grasslands in subtropical/subtemperate climates. There is enough rainfall to support the vegetation and the organisms that drive the decomposition process. Soils, especially topsoils, that are rich in organic matter appear dark in color and will show a gradual lightening with depth, which is very evident in this figure. Dark-colored soils absorb heat, warm up more rapidly, and cool down less rapidly. Plants such as grasses contribute to soil organic matter through their extensive fibrous root mats and, to a lesser extent, litter fall on the surface. Over time, soil under grasslands, such as Phaeozem or Kastanozems, and Chernozems can accumulate large amounts of soil organic matter. The conversion of natural grasslands to agricultural use causes considerable losses of organic matter.

Source: Photo by Jones, Breuning-Madsen, et al.^[2]

occur with certain pollutants, which limits the potential contamination of soil and groundwater. Finally, the biochemical structure of organic matter can help to buffer excessive acid or alkaline soil conditions (Fig. 1).

The amount of soil organic matter is determined by a balance between biological inputs (e.g., plant residues), the rate of humus formation and its loss, which comprises the decomposition of vegetation, and humus mineralization. Depending on the climate and land use, organic matter can remain stable in soil for long periods. However, the level of organic matter in soil can be manipulated through variations in input or output conditions. Several land management practices, such as the harvesting of crops or drainage, remove C from the soil. Minimal or no-till cultivation, mulching crop residues, crop rotation, and intercropping with perennials all enhance the formation and increased storage of organic matter in the soil. The drainage of peatlands leads to significant losses of organic matter and emissions of CO₂ to the atmosphere and should be avoided.

It is generally accepted that most soil organic matter contains between 40% and 60% C (by dry weight).

Soil Organic Carbon (SOC) and Soil Functions

Low levels of organic C in the soil are generally detrimental to soil fertility and water retention capacity and tend to increase vulnerability to soil compaction, which leads to increases in surface water runoff and erosion. Other effects

of low organic C levels are a reduction in biodiversity and an increased susceptibility to acidification and desertification. Climatic conditions strongly influence both the trends and rates of accumulation and transformation of organic substances in the soil.

Measuring C in Soil

Although there are some promising new technologies, soil C usually cannot be measured directly in the field. Samples must be collected (see below) and sent to a laboratory for analysis. The most accurate method for measuring soil C is through dry combustion in an elemental analyzer. These instruments heat a very small sample of dry pulverized soil to around 1000°C and then measure the CO₂ levels that are released through the combustion process. If the sample contains carbonates or inorganic C, then the soil is pretreated with hydrochloric acid to remove the inorganic compounds. Results are expressed as the percentage of C in the sample.

Traditional procedures for determining SOC are the loss on ignition (LOI) and Walkley–Black tests. However, both are less accurate than the elemental analyzer process described above. LOI measures the loss of weight of organic matter in a dry soil sample after it has been heated in an oven to around 400°C for a few hours. The Walkley–Black method uses potassium dichromate to liberate the C in a sample. As both of these tests only measure organic C, neither can extract all the C that is present in a soil sample.

Problems in Measuring C in Soil

While the C content for a specific location can be calculated accurately using the methodology described above, the result is only applicable to the sampling location. The inherent variability of soil across the landscape means that the soil characteristics may be quite different a few meters away from a sampling site, which means that the C content may also be different. Soil scientists often take several samples within a soil body to determine an average or “representative” C content or density for a particular soil type.

Calculating Soil C Stocks

The amount (or stock—t ha⁻¹) of SOC can be calculated to a given depth using the following equation:^[1]

$$\text{SOC} = C \times \text{BD} \times (1 - \text{VS}/100) \times T \times 10^2 \quad (3)$$

where C is the organic C content for a specific soil type (% weight) for a given depth—determined by laboratory analysis; BD is the soil bulk density (g cm⁻³)—a crucial factor that describes the weight of an undisturbed soil sample. Bulk density can range from 0.1 for light

peats to 1.8 for very dense, compacted mineral soils; VS is the volume of coarse fragments (and/or ice) in the soil (% volume)—a measurement recorded in the field; and T is the thickness of the soil layer (e.g., 0.30 m).

SOC is normally expressed in tonnes of carbon (tC) and gigatonnes (Gt = 1 billion tonnes), but data are also presented in megatonnes [1 million (10^6) tonnes], petagrammes (Pg = 10^{15} g), or teragrammes [Tg = 10^{12} g equivalent to 1 billion (10^9) kilograms].

SOC IN AFRICA: A PERSPECTIVE

One of the most striking features of African soils is the huge range in values and the diversity in the distribution of SOC. The map shown in Fig. 2 was produced for the published Soil Atlas of Africa^[2] and presents the distribution of SOC densities in Africa to a depth of 100 cm from the surface in tonnes C per hectare ($t\ C\ ha^{-1}$) with a resolution of 3 arc seconds. The values shown on the map are based on data from an amended version of the Harmonized World Soil Database (HWSD).^[3]

The colors on the map correspond to the amount of organic C in the soil. Lighter tones indicate the lowest concentrations of organic C, while darker tones indicate higher amounts. SOC varies according to temperature, moisture, local soil conditions, and land use. Most of the C stock of the continent is located in Central Africa. Levels for much of northern and southern Africa are relatively low. Values range from very low or negligible levels in the deserts of the Sahara, the Kalahari, and the Horn of Africa

to very high in the wetlands of Sudan (Sudd), Democratic Republic of Congo (Ngiri–Tumba–Maingombe), Congo (Sangha–Nouabale–Ndoki), Rwanda, Burundi, Tanzania, and the Barotse Floodplain in Zambia.

The following four main zones stand out: the very low arid regions, temperate grasslands, tropical forests and grasslands, and wetlands. The maximum SOC densities were found in Rwanda ($214.6\ t\ C\ ha^{-1}$) and Burundi ($166.7\ t\ C\ ha^{-1}$), while the minimum SOC densities were found in arid Djibouti ($15.1\ t\ C\ ha^{-1}$) and Mauritania ($20.3\ t\ C\ ha^{-1}$). The average SOC content is 35.08 and $31.83\ t\ C\ ha^{-1}$ for the 0–30 cm and 30–100 cm soil layers, respectively.

The soils of the tropical zone contain slightly more C than the soils of the savannah regions. The impact of land use change on C varies depending on the type of change. The conversion of tropical forests into farmland reduces topsoil C content by 20–50% of the original levels through reduced production of detritus, increased erosion rates, and increased decomposition of soil organic matter by oxidation. Deeper layers tend to be less affected. The conversion of forests to pasture appears not to change soil C dramatically and may even increase levels in some cases but may affect other issues (e.g., biodiversity and erosion).^[4–6]

From the amended version of the HWSD, soil C stocks for continental Africa have been calculated as $80.1\ Gt\ C$ for the 0–30 cm layers and $74.5\ Gt\ C$ for the depth 30–100 cm (this gives a total of $154.6\ Gt\ C$ for 0–100 cm depth). The soils of the Democratic Republic of Congo and Sudan hold the most SOC with 19.11 and $12.65\ Gt$, respectively.

Fig. 2 The map shows organic C in the uppermost 100 cm of soil. Organic C held deeper than 100 cm (e.g., deep peats and estuaries) is not counted in this exercise. Consequently, there is more soil C in reality than shown in this map. Abrupt boundaries in the map may reflect disparate soil data sets.

Source: From Jones, Breuning-Madsen, et al.^[2] and Hiederer & Kochy.^[3]

The reader should note that there are uncertainties in any estimate of soil C stocks at national and continental scales, and the uncertainty of the information presented here is high. More confidence can be attached to information from regions with more detailed soil inventories (the Mediterranean parts of North Africa, South Africa, and parts of Eastern Africa).

In comparison, various estimates^[7] place the total terrestrial organic C pool of Africa (this includes aboveground vegetation and also all SOC, not just that in the upper 1 m) at between 250,000 and 280,000 Gt.^[4] In this context, soil holds between 55% and 70% of the total African terrestrial organic C pool.

SOC and Soil Type

It is clear from the earlier text on soil-forming factors and soil processes that organic C content will vary according to the type of soil. Histosols in Africa (by definition soils rich in organic matter) can contain close to 100 kg C m⁻², while Gypsisols (a desert soil containing high levels of gypsum and found only in very arid climates) typically contain only around 1 kg C m⁻².

In addition, SOC varies with depth and soil type. In Leptosols (shallow soils over hard rock or gravel), virtually all of the SOC are located in the 0–30 cm layer. In contrast, Histosols (organic soils also known as peat) can be several meters thick.

SOC and Ecosystems

The relationship between SOC content and ecosystems shows some interesting features. Using the World Wide Fund for Nature’s Terrestrial Ecoregions of the World database as a base, the soils with the highest mean SOC

content, as expected, are found in the wet mangrove ecosystem with a mean C content of 6.61 kg m⁻². Similarly, there is no surprise that the deserts and dry shrubland ecosystem exhibit the lowest C content with only 1.53 kg m⁻², reflecting the limited biomass production and poorly developed soils of arid regions. Higher net primary production in tropical regions, coupled with deep soils, gives very high C content to the soils of tropical and subtropical moist broadleaf forests (5.7 kg m⁻²). Soils in tropical and subtropical dry broadleaf forests (5.0 kg m⁻²) and flooded grasslands and savannahs (4.17 kg m⁻²) also contain significant levels of SOC, while levels are significantly lower in Mediterranean forests, woodlands and scrub (2.83 kg m⁻²), and montane grasslands and shrublands (3.47 kg m⁻²).^[8]

However, total SOC stocks also depend on the geographical extent of a soil. In this context, Fig. 3 demonstrates that the most important stock of soil C to a depth of 1 m is stored in the tropical and subtropical grasslands, savannahs, and shrubland ecosystems, holding around 80,000 Tg C. Due to their small extent, the temperate coniferous forests and mangrove ecosystems contain relatively small C stocks. Further investigation of the distribution of C within soil shows that in all ecosystems, SOC is concentrated in the topsoil. The slightly higher values in the subsoils of flooded grasslands and tropical moist broadleaved forests may reflect conditions that facilitate the leaching of C deeper into the soil (however, the reader should note that the values for the subsoil relate to more than twice the depth of the topsoil). These figures demonstrate that the topsoil is the most important SOC pool, yet it is also the most susceptible to manipulation by human activities and climatic variations which, together or singularly, can lead to the loss of soil C and degraded soils.

Fig. 3 Topsoil and subsoil organic C stocks in major African ecosystems. Source: From Jones, Breuning-Madsen, et al.^[2]

Fig. 4 A global perspective of Africa with regard to C. For comparison, the soils of the northern circumpolar regions (i.e., above a latitude of 50° North) contain about 25% of the global terrestrial vegetation C and approximately 50% of the terrestrial soil C pool. It should be noted that data for African pools and sinks are very imprecise and that the uncertainties associated with these values can be very large.
Source: From Jones, Breuning-Madsen, et al.^[2]

THE SOILS OF AFRICA IN THE GLOBAL C CYCLE

Fig. 4 presents a global view of Africa from a C perspective. While occupying 20% of the earth's land surface and being home to 14% of the world's population, Africa contributes only 4% of the global fossil fuel C emissions that are responsible for rising atmospheric CO₂ concentrations (0.2 Pg C yr⁻¹). This is a disproportionately small fraction but reflects the rural and underdeveloped nature of the African population. However, Africa generates more than one-fifth of the global emissions from land use (i.e., deforestation and land use change) and, staggeringly, nearly 40% of global emissions from burning biomass (i.e., deforestation, shifting cultivation, savannah fires, fuel wood, and agricultural residues). Both the vegetation and the soils of Africa occupy a similar global proportion, about 13% and 10–12%, respectively.^[7,9,10]

In general terms, Africa emits slightly more C on an annual basis than it sequesters. While soil is by far the largest store, holding an estimated 200 Gt of C, soils are also the largest emitter of C in Africa with 11 Gt C primarily due to microbial or heterotrophic respiration and decomposition of organic matter. However, this amount is almost offset by plant productivity (net primary productivity). On the other hand, C emissions due to land clearance and the

burning of biomass are markedly higher than emissions due to the combustion of fossil fuels (e.g., oil and gas). While they affect large areas, emissions from savannah fires are offset by the subsequent regrowth.

Fig. 5 shows the amount of C stored in the soil (to a depth of 1 m) and vegetation of the main ecosystems of the planet.^[11] The figure clearly illustrates the huge capacity of soil to store C compared to vegetation and emphasizes the key role that soil plays in the terrestrial global C cycle. The only ecosystem approaching parity between C stores in vegetation and the soil is the tropical forest. This is due to the lush and continuously growing vegetation, and the rapid recycling of litter and plant remains in the soil. However, the figure also shows clearly that the main reservoirs of global land-based C are the cold permafrost regions and ecosystems such as the boreal forests.

CONCLUSION

Fluxes associated with the SOC reservoir of Africa are significant in the global climate system. In general terms, Africa emits slightly more C on an annual basis than it sequesters. Soil is by far the largest store, holding an estimated 200 Gt of C, with vegetation accounting

Fig. 5 A comparison of organic C pools in the soil and the vegetation of major ecosystems. Permafrost-affected soils are the principle terrestrial C pool, while in the tropics, there is a balance between the two pools.

Source: EC Joint Research Centre.^[11]

for around 80 Gt C. With 11 Gt C, soils are also the largest emitter of C in Africa primarily due to microbial or heterotrophic respiration and decomposition of organic matter. However, this amount is almost offset by plant productivity (net primary productivity). On the other hand, C emissions due to land clearance and the burning of biomass are markedly higher than emissions due to the combustion of fossil fuels (e.g., oil and gas). While they affect large areas, emissions from savannah fires are offset by the subsequent regrowth.

While these data suggest only a small C imbalance across Africa, climatic fluctuations (especially drought) can lead to sizeable changes in net ecosystem productivity and increase in wildfires. In these situations, the land system of Africa becomes a major source of global C emissions. Considering the existing and increasing pressures on land across Africa (climate variability, land use change, population growth, industrialization, and urbanization), C emissions are likely to undergo substantial changes over the coming years.

The reader should note that there are uncertainties in any estimate of soil C stocks at national and continental scales, and the uncertainty of the information presented here is high. More confidence can be attached to information from regions with more detailed soil inventories (the Mediterranean parts of North Africa, South Africa, and parts of Eastern Africa).

Significant additional effort and investment are required to improve these estimates and spatial resolution of the soil biophysical properties in order to better quantify the impact of human activities on the SOC reservoir of Africa.

ACKNOWLEDGMENTS

This entry builds on the considerable knowledge on soils in Africa that has been amassed through the substantial endeavors of many individuals and organizations from across Africa and Europe. The authors would like to thank everybody who shared their knowledge. In particular, the Joint Research Centre is grateful for the support and commitment offered by the Editorial Board of the Soil Atlas of Africa, the Food and Agriculture Organization of the United Nations, the African Soil Science Society, and the African Union Commission.

Abstract

Sequestration of soil organic carbon (SOC) is vital to increase the SOC stock and quality, decrease soil erosion, and mitigate climate change. In this entry, we reviewed the level of soil degradation and the loss of SOC in Ethiopia. Results of studies on land use types are summarized to sort out those sound types that can potentially reverse the SOC loss in various ecosystems of the country. The SOC loss through soil erosion, deforestation, and land use change is estimated to be from 15 to 1000 kg ha⁻¹ yr⁻¹ in Ethiopia. Much of this loss in SOC can be attributed to reduced inputs of organic matter, increased decomposability of crop residues, and tillage effects that decrease the amount of physical protection to decomposition. The problem of SOC depletion in Ethiopia can be tackled through better management aimed at augmenting the normal function of the soils and SOC sequestration. Land use types such as native forest, grass land, plantation forest, agroforestry, and woodlands better protect the soil from severe erosion and augment the accrual of SOC. Restoration of severely degraded lands through area closure is good option to enhance SOC sequestration if it is practiced in areas where the soil depth class falls below 35 cm. We suggest that appropriate policy should be launched to safeguard very sloppy lands from cultivation. Along with biological and physical conservation measures, cow dung and crop residues should be returned to the cultivated crop fields to enhance the sequestration of SOC and sustain agricultural productivity.

INTRODUCTION

Ethiopia, with an estimated population of 100 million, is located in the Horn of Africa (Fig. 1). It is bordered by Eritrea to the north, Djibouti and Somalia to the east, Sudan and South Sudan to the west, and Kenya to the south. The nation's topographic features are dominated by rugged mountains and lowland plains. Based on major landforms and altitudinal variations, the soils of Ethiopia can be grouped as highland and lowlands soils.

Montane forests are the main constituents of the natural vegetation, of which dry afromontane forms the largest part. The highlands of Ethiopia, in contrast to most mountain systems outside Africa, are very suitable for human inhabitation. About 14% of the population lives in areas above 2400 m (cool climatic zone), and about 75% lives between 1500 and 2400 m a.s.l. (temperate zone). The remaining 11% of the population resides in the lowlands which constitute 60% of the 1,270,000 km² total area of the country. Agriculture is the dominant sector of the nation's economy where the livelihood of the 85% of the population is reliant on. In general, the highland areas support 60% of livestock and 90% of the agriculturally suitable area of the

country. Favorable climate and ecological conditions, sufficient rainfall, moderate temperatures, and well-developed soils were the basis for the early development of agricultural systems in the highland areas. Keeping up with the steady population growth, agriculture generally expanded from gently sloping land onto the steeper slopes of the mountains. The clearing of forests, traditional tillage practices, overgrazing, and the subsequent erosion process over long periods of time gradually destroyed the soil resource.

Soil erosion has reduced the soil organic matter (SOM) layers in the highland areas across the country. Originally, the highland soils of Ethiopia were more than 50 cm deep and probably had rooting depth of more than 100 cm that leads to the conclusion that the range of depth classes shown in Table 1 represent the legacy of soil degradation through erosion process. Deforestation, soil erosion, traditional tillage practices, and overgrazing are ongoing and are reducing the soil quality (health) through the loss of SOM. Soil quality (health) is defined as *the capacity of a soil to function within ecosystem and land use boundaries, to sustain biological productivity and maintain environmental quality*.

Fig. 1 Location of Ethiopia on earth.

SOM influences several critical soil functions and is affected by land use and land management practices. Decreases in SOM contents, through cultivation or tillage intensification, are often related to the deterioration of soil structure. Effects include the loss of aggregate stability, increased crust formation, increased runoff and soil erosion, slower water infiltration, and a slower exchange of water/gasses. Different organic matter pools such as particulate organic carbon (POC; organic fraction >53 μm diameter, recognizable structure) and humic fraction [non-identifiable chemical structure such as humic acids (HAs) and humin (HU)] affect different soil functions.

POC is important in providing energy for biological processes. The humic fraction is an important source of essential soil nutrients and is the principal pool in contributing to the soil's cation exchange capacity.

The loss of SOM and the little or no input to compensate the loss deplete the soil carbon (C) stock [mass of organic C stored in the soil C pool (or reservoir)], which is a phenomenon in the highland and lowland areas of Ethiopia. C exists in the environment in many forms, predominantly as a plant biomass, SOM, geologic deposits, and atmospheric carbon dioxide (CO_2) gas, and dissolved in seawater. On the other hand, sequestration of C (storage of C in a stable solid form) in soil and vegetation is a necessity for improving soil quality and mitigation of climate change. Soil is the largest overall reservoir of C and a major source and sink for C exchanges between the atmosphere, terrestrial vegetation, and aquatic environments.

Depending on land use type and topographic features, soil erosion and cultivation of fragile lands such as sloppy terrain cause decline in soil quality and depletion of soil organic carbon (SOC). Much of this loss in SOC can be attributed to reduced inputs of organic matter, increased decomposability of crop residues, and tillage effects that decrease the amount of physical protection to decomposition. The changing climate on soils also exacerbates the problem of increasing SOC loss through its effect on soil moisture and temperature regimes. In this entry, we discuss the overriding factors that control the SOC loss such as deforestation, soil erosion, and cultivation of fragile lands and summarize some study findings on land use types that can potentially recover the soil C lost as a result of mismatch of management and land use type in Ethiopia.

SOIL DEGRADATION IN ETHIOPIA

The highlands of Ethiopia constitute more than 44% of the total area of the country.^[2] Vegetation and soil degradation are serious problems in both the highlands and lowlands of Ethiopia. Nationally, the conservative deforestation rate of natural forests is estimated to be 0.16–0.20 million ha yr⁻¹, and the natural forest cover is believed to have decreased from 16% in the 1950s to about 2.8% in 1980s.^[3] From the information available, the rate of deforestation in Ethiopia is alarming, and the rate of afforestation is very negligible. A satellite image from 1986 to 2000 shows that Ethiopia's forest cover has been reduced to 2.36% or 27,059 km² from 1990 to 2000.^[4] The growing demand of the ever-increasing population for grazing and arable land, fuel wood, and construction material is the major factor contributing to deforestation in Ethiopia.^[5,6] Fuel wood has become scarce to a large number of the Ethiopian households. Thus, rural people use dung and agricultural residues as alternative fuels instead of putting them back into the soil to increase crop yields. The demand for forest product is growing, and as a result, the remnant forests are under heavy pressure of massive deforestation in the country (Fig. 2).

Deforestation and the subsequent cultivation of fragile lands accelerate the rate of soil degradation through erosion process. Processes of soil degradation include erosion by water and wind, loss of soil physical and chemical properties necessary to maintain soil quality (health), loss of nutrients, and SOC depletion.^[7]

The poor land cover and traditional farming practice have aggravated soil erosion, resulting in the reduction of the soil depth layers across the country. Hurni^[1] has pointed

out that the rooting depth below 50 cm (Table 1) has significant negative effects on soil productivity due to loss of SOM. The loss of SOM reduces the water-holding capacity of soil during periods of intermittent rainfall that makes it difficult to be available at times of draught. Regions that have areas with depths less than 10 cm make them unsuitable even for moderate grassland use or afforestation.^[1,2] Estimates of soil loss from Ethiopian highlands and lowlands vary widely. The rate of soil loss by erosion documented for different land use types in Ethiopia ranges from 16 tons to 300 tons per hectare per year.^[1] Based on this range, the amount of annual soil loss by erosion is estimated to be from 1248 million tons to 23400 million tons per year from the 78 million hectares of cultivated, grazing, and range lands.

The Ethiopian highlands reclamation study^[2] suggested the annual average rate of 100 tons per hectare per year soil loss for different land use types in the country. Based on this rate, the total soil loss is 7800 million tons per year from cultivated, grazing, and range lands of Ethiopia.^[8] The soil degradation through water and wind erosion in lowland soils is caused by the poor farming practices particularly in the areas practicing cereal monoculture farming system, uncontrolled burning of range lands, conversion of woodland and native forests into crop lands, and burning dung and crop residues for household energy needs.^[2] Land degradation is seriously threatening the economic and social development of the country as a whole. Due to degradation, an increasing number of Ethiopians befall to be vulnerable to the effects of draught. The severity of the devastating draught and the resulting famines in the past, present, and beyond can be attributed to an accelerating process of soil degradation.

LOSS OF SOM IN ETHIOPIAN SOILS

It is well documented that SOM is accumulated more in the upper most soil layer and decreased downward to 1 m depth.^[9,10] The reduction of soil depth from 100 cm to 10 cm (Table 1) implies that the available SOM is washed away downslope. Comparatively within the Ethiopian highlands, the effect of soil erosion is more severe in Welo, Hararghe, and Shewa (Table 1). The legacy of soil erosion is more pronounced in Welo region where 72% of the total highland area has a soil depth class of 10 cm (Table 1). The SOM loss associated with the removal of surface soil ranges from 15 to 1000 kg ha⁻¹ yr⁻¹ which amounts to 1.17 to 78 million tons of organic matter lost per year from 78 million hectares of cultivated, grazing, and range lands. The loss of soil nitrogen (N) ranged from 0.39 to 5.07 million tons per year and phosphorus from 1.17 to 11.7 million tons per year.^[8] The Ethiopian highland reclamation study^[2] put the degraded area on the highlands at 27 million hectares, of which 14 million hectares is very seriously eroded with 2 million hectares of this having reached a point of no return.^[8]

Conversion of native forest and woodlands into cultivated lands increases the loss of SOM (Table 2). Spaccini et al.^[11] assessed the influence of deforestation and the subsequent cultivation on total SOC and humus fraction (the stable fraction of SOM) under different soil and vegetation types from five locations in Ethiopia (Table 2). Spaccini et al. found that organic C concentration was

invariably higher under forest setting compared with that under cultivated fields. The finding also shows that HA, fulvic acid, HU, and humic hydrophobic fraction extracted with an acetone–hydrogen chloride solution were decreased in cultivated lands in all locations, but the magnitude of decrease was site-specific (Table 3). However, data in Tables 2 and 3 shows that there is also variation within the forest and the cultivated fields of the different sites that could be attributed to difference in soil type, rainfall amount, and distribution. The data reported by Spaccini et al.^[11] are in line with the finding reported by Demessie.^[12] Demessie has evaluated the soil C and N stock under natural forest, plantations, agroforestry, and cultivated land use types located under similar site characteristics. The sites were adjacent to each other having similar Andic Paleustalf soil and located within an altitudinal range of 2137 to 2215 m a.s.l. All sites were receiving the same average annual rainfall of 917 mm. Demessie found that the SOC was higher under natural and plantation forests compared with those under traditional agroforestry and monocropped cultivated fields (Fig. 3). The variation seen could be attributed to difference in land use type, implying that conversion of native vegetation to cultivated lands will reduce SOM and other physical and chemical properties of soils regardless of differences in magnitude due to site properties. If properly managed, woodlands in lowland areas sequester more SOC. For example, Lemenih and Itanna^[13] showed that acacia woodland soil sequestered 40.3 Mg C ha⁻¹ and 5.3 Mg N ha⁻¹ under the semiarid

Table 3 Changes in humic fractions of stable SOC in different locations of Ethiopia.

environment in the rift valley of Ethiopia. Similarly, Michelsen et al.^[14] evaluated C stocks, microbial respiration, and biomass in fire-prone tropical grassland, woodland, and forest ecosystems in the lowlands of Western Ethiopia. The forest and woodland ecosystems sequestered more SOC than the other land use types. From the foregoing discussion of research findings, it can be concluded that the storage of SOC in Ethiopia may be enhanced by reducing C losses through restoration of vegetation on degraded lands.

POTENTIAL OF SOIL C SEQUESTRATION THROUGH REHABILITATION OF DEGRADED LANDS IN ETHIOPIAN SOILS

C sequestration refers to long-term storage of CO₂ to mitigate or deter global warming and avoid the harmful effect of climate change. The principal global C pools are in the order of oceanic, geologic, pedologic (soil), biotic, and atmospheric pool. The SOC concentration ranges from a low in soils of the arid regions to high in soils of the mild climatic regions (the highlands for Ethiopia's case) and extremely high in organic or peat soils.^[15] Soil C plays an important role in the maintenance of agricultural productivity under changing climatic conditions and is an element of the mitigation and adaptation response in the land use sector.^[16] In particular, the maintenance of existing C stocks as well as soil C sequestration can contribute to improving and/or sustaining agricultural productivity, reducing greenhouse gas emissions, and increasing the resistance and resilience of agricultural ecosystems against climate change impacts, such as rising temperatures, increased frequency of flooding, and other extreme weather events. All fertile soils have an adequate supply of organic matter that includes plant and animal residues at various stages of decomposition, cells (living and dead) and tissues of microbes, and substances synthesized by soil population.^[17]

Sequestration of SOC is therefore fundamentally important to decrease soil degradation, increase the SOC stock, increase productivity, and mitigate climate change.^[15,18,19] It is well documented that land use types such as native

forest, grass land, plantation forest, agroforestry, and woodlands better augment the accrual of SOC through litter input, lower temperature that reduces high rate of decomposition, and protection of soil from severe erosion.^[9,10,20] Degraded lands can be restored through sound management and judicious land use practices.

Land use, soil type, climate, and vegetation are the drivers of SOM dynamics.^[21] Wherever one of the land use changes decreased soil C, the reverse process increased soil C and vice versa.^[9] For example, a study result reported by Demessie^[12] showed that plantations established on cultivated lands accrued SOC in 25–30 years times the amount very close to the natural forest (Fig. 3). A change in land use from agriculture to forestry is replacing the annual cycle of cultivating and harvesting crops by the much longer forest cycle.^[22] This enables the production of a larger biomass and reduces the degree of soil disturbance. On the other hand, the conversion of natural vegetation to cultivated land results in very rapid declines in SOM, reduced inputs of organic matter, increased decomposability of crop residues, and tillage effects that decrease the amount of physical protection to decomposition.^[22,23]

Consequently, restoration of degraded soils in Ethiopia is a vital strategy to reduce soil erosion and environmental degradation and to improve soil productivity. Such management accentuates the potential of Ethiopian soils to provide terrestrial sinks of C and reduce the rate of enrichment of atmospheric CO₂. SOC contents decrease by 0–63% following deforestation.^[7,10,11] There exists a high potential for increasing SOC through the establishment of natural or improved fallow systems (agroforestry) with attainable rates of C sequestration in the range of 0.1 to 5.3 Mg C ha⁻¹ yr⁻¹.^[7] The accumulation and turnover of SOM are major factors in soil fertility and ecosystem functioning and determine whether soils are sinks or sources of C in the global cycle.^[23]

The turnover of C in soils is controlled mainly by water regimes and temperature but is modified by factors such as size and physicochemical properties of C additions and distribution of litter within the soil matrix and its interaction with clay surfaces.^[24] Substantial fraction (often 30–50% or more) of the energy and C annually fixed in forests is contributed to the forest floor as litter fall (mostly) leaves.^[25]

The sequestration of SOC can be greatly enhanced when degraded soils and ecosystems are restored; marginal agricultural soils are converted to a restorative land use or replanted to perennial vegetation.^[15] When food production is a priority, agroforestry systems can be used as an alternative for economically friendly land use approach in cultivated lands. For example, a study result by Demessie et al.^[10] on parkland type of agroforestry system in Gambo district of Southern Ethiopia suggest that the SOC and N stocks tended to be less in farmlands than in the parkland agroforestry system, although the difference is not significant (Fig. 4). In this particular study site, the soil in

Fig. 4 Total SOC stock of 1 m depth in the chronosequences of agroforestry (AF) and farm (F) land uses. Means followed by the same lower case letter(s) are not significantly different at ($P < 0.05$).

Source: From Demessie, Singh, et al.^[10] 2013 Springer.

parkland agroforestry systems is equally subjected to soil disturbance through tillage practices exposing the SOM for decomposition. However, even the slightest increase of SOM through the addition of litter to the soil will have positive effect on the soil quality compared with the treeless cultivated land where little or no crop residue is returned to the soil. When the soil disturbance through tillage practice is minimum, the C sequestration potential of agroforestry systems is estimated to be between 12 and 228 Mg C ha⁻¹.^[26,27]

Cow dung and crop residues should be returned to the cultivated crop lands along with biological (wind break and shelter belts) and physical conservation measures. Area closure (an area delineated to exclude human interference) should be adapted to areas where the soil depth class falls below 35 cm and appropriate policy should be launched to safeguard very sloppy lands from cultivation. For example, Descheemaeker et al.^[28] have shown that the establishment of area closures has become an important measure to increase SOM and N compared with the degraded grazing land in the Tigray highlands of northern Ethiopia (Fig. 5). This suggests that such sound and environmentally friendly land management practices will possibly enhance the potential sequestration of C in Ethiopian soils. More research has to be done on management practices to explore those suitable to SOC sequestration and maintenance of soil quality for different soils and ecosystems in the country.

Abstract

Inherent soil heterogeneity makes tracking carbon (C) through these dynamic environments very difficult. Here we discuss three emerging techniques for spatially resolved analysis of organic components in soil. Laser ablation isotope ratio mass spectrometry (LA-IRMS) is a method for performing stable isotope analysis on solid samples. The laser-based sampling associated with LA-IRMS allows targeting of specific regions along a solid surface, with resulting isotope analysis at a spatial resolution of up to 50 μm . Laser ablation aerosol mass spectrometry (LA-AMS) uses a similar, laser ablation-based, sampling approach with up to 2 μm spatial resolution. In contrast to LA-IRMS, which provides isotope measurement but no chemical identification, the high resolution mass spectrometry capabilities of the AMS enable basic identification and classification of organics based on their elemental ratios (C/N, O/C, H/C, etc.), degree of oxidation, or inclusion of functional groups (e.g., amines, hydrated species, etc.). Nanospray desorption electrospray ionization mass spectrometry (nano-DESI) offers additional detail to chemical identification above that provided by AMS. This technique applies a solvent bridge to dissolve organics off of a solid's surface. A high voltage applied between the solvent droplet and detector inlet then aspirates the analytes into the mass spectrometer for chemical identification. Translating the solvent bridge over a sample's surface enables spatial ($\sim 100 \mu\text{m}$) resolution in organic compound analysis. Taken together, the spatial resolution of these emerging approaches, combined with their associated isotopic measurement and chemical identification, provides a suite of tools to enhance the understanding of C accumulation, localization, and transformation in soils.

INTRODUCTION

Soils hold an extremely large reservoir of organic carbon (C), with the overall net balance being both influenced by and potentially directing global-scale climate modification. Despite its central role in C-cycling, a complete set of key principles controlling the fate of soil organic C remains elusive in large part due to the inherent geochemical, organic matter, and microbial heterogeneity of soil systems. Here we present an overview of three spatially resolved techniques that can be used to monitor soil organic C found in such heterogeneous environments. The first technique, laser ablation isotope ratio mass spectrometry (LA-IRMS), can be used to spatially track stable isotope substrates/labels as they migrate into soil systems. Laser ablation aerosol mass spectrometry (LA-AMS) enables the identification of dominant organic compounds at high spatial resolutions. Nanospray desorption electrospray ionization (nano-DESI) permits high mass resolution chemical structure identification of solvent-soluble organics, also at fine-scale spatial resolution. Combined, these emerging tools provide a spatial framework for constraining both the

fundamental organic components of a soil and for testing the reactivity and accumulation of added (and potentially isotopically labeled) C sources into a soil.

LA-IRMS

Stable isotope analysis has a strong history of tracking organic substrate turnover in soil, delineating rhizosphere activity zones, and identifying natural transitions in C inputs to a soil. When coupled with stable isotope probing, isotope analysis can be used to track an added substrate into a soil and help determine its fate—is it simply remineralized, spread throughout the soil system, or focused within specific organisms/spatial locations? Traditional bulk stable isotope methods use elemental analysis (EA) to convert organic C to carbon dioxide (CO_2) coupled to continuous flow isotope analysis by IRMS. While this permits precise isotope measurements, the approach is limited in spatial resolution by a combination of physical separation techniques (manual dissection) and the overall EA-IRMS measurement sensitivity (typically on the order of 10^3 s of $\mu\text{g C}$).

To achieve better spatial resolution, the LA-IRMS uses a laser ablation system coupled with an optical microscope to image the surface of a solid sample, spatially identify a target for analysis, and then selectively sample the region for isotope analysis. Moran et al.^[1] described the basic components of an effective LA-IRMS system. A solid sample is placed in an ablation chamber designed to enable optical imaging (through quartz windows) while immersing the sample in a turbulent helium flow. A neodymium-doped yttrium aluminum garnet (Nd:YAG) laser ($\lambda = 266$ nm) is used to ablate a targeted portion of a sample's surface at a variety of different spot sizes ranging down to 50 μm . Importantly, the ablation process produces almost entirely small particulates (10's nm diameter) with very little production of volatile organic C compounds so that the large majority of the sample is preserved in the particulate phase. The small diameters of these particulates enhance their mobility in the applied helium carrier which entrains and transfers the sample fragments to a micro combustion reactor (940°C) containing nickel and platinum catalysts in the presence of a small oxygen flow. Rapid combustion converts all organic material in the particulates to CO_2 , which is cryogenically trapped in a capillary immersed in liquid nitrogen. Following trapping, the helium flow rate is reduced such that when the sample-derived CO_2 is sublimated, it is entrained in a relatively low amount of carrier gas and transferred to an IRMS for isotopic analysis. This reduction in carrier gas effectively concentrates the sample-derived CO_2 , which enables more of the sample to enter the IRMS, thereby increasing overall sensitivity from 10's μg C (EA-IRMS) to ~ 65 ng C (LA-IRMS). Taken together, the LA-IRMS system offers isotope measurement precision and accuracy comparable to that of EA-IRMS

but with improved measurement sensitivity and, most importantly, the inclusion of spatial resolution.

Despite the spatial and sensitivity advantages, there are some limitations to the LA-IRMS approach. First, samples must be dried prior to analysis which stops microbial processes and may require a set of time series samples to be collected when monitoring the fate of applied substrates. Second, samples need to fit into an ablation chamber for analysis. Moran et al.^[1] described a chamber with a half inch diameter. While chambers could be constructed to enable analysis of larger samples, any such modifications would require attention to maintain a sufficient carrier gas flow to facilitate sample transfer of ablation particulates through the combustion reactor for subsequent analysis. Finally, suitable samples for LA-IRMS must maintain sufficient cohesion such that the violent ablation process does not destroy the sample's structure. Bruneau et al.^[2] applied a polyethylene glycol resin to soil samples to enhance their structural cohesion and reduce damage to the sample's structure during the ablation process. Despite adding exogenous C to the sample, the work demonstrates that the amount of added C did not preclude the tracking of ^{13}C -labeled CO_2 into root biomass.

The spatial resolution of LA-IRMS can be observed in previous ablations of a strand of hair (Fig. 1A) where each of the visible 50 μm ablation pits provided sample material for an individual $\delta^{13}\text{C}$ measurement. The ability to direct the ablation sampling allows any part of the sample's surface to be analyzed while minimizing collateral damage to the adjacent sample. Moran et al.^[3] demonstrated the use of LA-IRMS to track labeled ^{13}C -bicarbonate incorporation into biomass of a hypersaline, photoautotrophic microbial mat. Following the isotope analysis, the group successfully performed DNA extraction for sequencing from around the

Fig. 1 LA-IRMS image of post-ablated hair samples (A) and data resulting from analysis of ^{13}C -glucose treated soil (B). The position of ablation pits in a strand of horse hair (A) is completely controlled by the user and can be aligned at any position over the sample's surface. Minimal damage was observed around the ablation pit and previous work on microbial samples has demonstrated successful extraction of DNA from sites surrounding the pits. Application of glucose solutions (B) containing different amounts of ^{13}C highlight the ability of LA-IRMS to differentiate between samples of varying ^{13}C content. The accuracy and precision of the approach require a much lower level of labeling for successful tracking (previous accuracy was demonstrated at better than 0.5‰).

ablation pits, demonstrating minimal damage to the surrounding sample by ablation. Thus, while LA-IRMS may not be considered non-destructive, it can be described as minimally destructive outside of the 50 μm ablation target.

One key capability of the LA-IRMS system is the spatial tracking of labeled C as it moves into a soil community. Previous work (Fig. 1B) applied various amounts of ^{13}C -glucose to the surface of two different soil types (a sand and a loam). Once dried, LA-IRMS was directed to the samples to measure the resulting ^{13}C content and, as shown, increasing amounts of label was easily measured in both the types of soil and the matrix effect of the soil did not inhibit isotope quantification. Moran et al.^[3] used a time series approach for tracking the uptake of bicarbonate into a phototrophic microbial mat. They found that integration of the LA-IRMS results across a depth profile of the mat showed isotopic agreement with EA-IRMS analysis of the entire mat segment. The added spatial resolution of LA-IRMS, however, was able to pinpoint the location of bicarbonate accumulation in the mat while spatially linked time series samples provided insight to the migration of the label through different layers of the stratified biomass. By providing spatially resolved isotope quantification, LA-IRMS can be used to track label incorporation into a soil as well as its subsequent migration or localization of the applied C.

LA-AMS

LA-AMS is an outgrowth of previously mentioned work^[1] The Aerodyne AMS was originally developed for characterization of the size and composition of atmospheric aerosols. In the work by Moran et al.,^[1] the AMS was used to demonstrate that ultraviolet laser ablation of organic and biological samples yields particles with a mode aerodynamic diameter of 100–200 nm, similar to the diameters obtained by LA of more refractory samples such as glasses and minerals.^[4] Furthermore, the EA of these particles was

shown by mass spectrometry to reflect that of the bulk sample, leading to the investigation and development (underway) of LA-AMS for the spatial and bulk characterization of biological and other organic samples such as plants, roots, fungi, and organic matter in soil.

LA-AMS uses an Aerodyne high-resolution time-of-flight AMS (HR-ToF-AMS; Fig. 2A) which is capable of providing real-time *in situ* measurements of total mass, size distributions, and chemical composition of aerosol particles.^[5] Even though the AMS undergoes continual development as higher resolution mass spectrometers come to market, the basic particle detection scheme remains consistent. The AMS uses an aerodynamic lens to sample submicron particles into vacuum, where they are aerodynamically sized based on ToF measurements before being thermally vaporized on a heated surface and chemically analyzed via electron ionization (EI) mass spectrometry. Due to the use of thermal vaporization, the HR-ToF-AMS is most effective for detecting non-refractory, more volatile organic species in particulate matter. EI leads to substantial fragmentation of the analyte ions such that the molecular ion appears along with many fragment ions, which is problematic especially for complex organic mixtures. EI has benefits over other techniques, however, by being sensitive to nearly all organic species and having a nearly constant response factor over a wide range of chemical compositions, minimizing the use of calibrations and/or standards. Together, these attributes enable the total mass of complex aerosol mixtures to be measured without calibration of individual species or the use of a large number of standards. Due to sample fragmentation by EI, the mass spectra are composed primarily of fragments of larger compounds. However, by employing high-resolution mass spectrometry, the identities of different ion fragments at the same nominal m/z can be determined, allowing for the determination of classes of compounds including hydrocarbons, nitrates, amines, sulfates, and chlorides as well as the measurement of elemental ratios (e.g., O/C, H/C, and N/C) within organic mixtures.

Fig. 2 Schematic of (A) the HR-ToF-AMS showing the sample inlet, aerodynamic lens, particle sizing, vaporization and electron impact ionization, and time-of-flight mass spectrometer and (B) the HR-ToF-AMS interfaced to an LA system. The current LA-AMS uses an excimer-based LA system (Photon Machines G2) with resolution down to 2 μm .

Fig. 3 Spatially linked LA-AMS time series of chemical families identified within a soil aggregate (A) obtained from the ablated sites as pictured in the inset. Chemical families include key ion fragments as determined by the AMS: CH (unoxidized hydrocarbons), $\text{CHO}_{n=1}$ (singly oxidized hydrocarbons), $\text{CHO}_{n>1}$ (multiply oxidized hydrocarbons), CHN (amines), $\text{CHNO}_{n=1}$ (organic nitrates), OH (hydrated species), and NH (ammonia). These can be related to their parent compounds such as alkanes, aldehydes, alcohols, carboxylic acids, and contaminants like polycyclic aromatic hydrocarbons (PAHs). The excimer laser is focused to 10 nm and is operated in a 3-second cycle beginning with a burst of 20 shots (1 second), followed by a 2-second rest to allow the transfer line to clear. The identities and abundances of the ions identified in the spatially linked mass spectra are used to produce chemical maps (B) that are related to spatial properties of the soil aggregate.

In typical applications, the AMS samples directly from the air at atmospheric pressure. The ability to analyze samples under ambient atmospheric conditions permits direct coupling of the AMS to a laser ablation output (Fig. 2B) without requiring any further sample preparation or purification. Furthermore, the rapid real-time response of the HR-ToF, acquiring 10,000 or more mass spectra per second, allows fast scanning of the laser over a sample surface. The known scan rate of the laser can then be used to create a spatial map (Fig. 3A) of elemental and molecular ratios of key species present in the sample with a sensitivity of 0.1 ng or less. Although preliminary, these results demonstrate how LA-AMS can be used to answer crucial questions in soil science such as correlations (Fig. 3B) between species indicative of microbial mass. An additional capability of LA-AMS is the ability to depth profile with a resolution of down to 100 μm , opening up the possibility of 3-D mapping correlating to morphology in combination with a non-destructive method technique such as X-ray tomography.

NANO-DESI

Nano-DESI^[6,7] is a technique for analysis of organic and biological molecules on surfaces. It is complementary to the ability of LA-AMS to measure fragmentation mass spectra at high lateral and depth resolution by having the capability to determine the identity of molecules on a sample surface by soft method electrospray ionization, which causes little or no molecular fragmentation, coupled to an ultrahigh-resolution mass spectrometer. Nano-DESI uses a solvent

bridge (Fig. 4) composed of a small ($\sim 100 \mu$) solvent droplet formed between two capillaries to dissolve molecules off the sample's surface. The analytes are then aspirated into the inlet of a mass spectrometer by a high voltage applied between the mass spectrometer and the primary capillary which also supplies solvent to maintain the droplet on the sample surface. The droplet can be translated across the sample to spatially resolve the sample's molecular composition and different solvents (i.e., polar vs. non-polar) can be applied to selectively dissolve/analyze different chemical classes. Nano-DESI is capable of detecting small ($<10 \text{ ng}$) quantities of material. This method has

Fig. 4 Schematic of nano-DESI source configuration for analysis of substrate deposited analyte.

been applied to a number of sample types including soil, atmospheric aerosols,^[6] and spatially resolved analysis of metabolites in bacteria grown on agar plates.^[8]

In the work by Lanekoff et al.,^[8] nano-DESI was used to spatially profile chemical gradients generated by microbial communities grown on agar plates. Nano-DESI allowed the determination of metabolites from colonies of living *Synechococcus* sp. PCC 7002 and, by not impacting viability of the cultures, enabled time series analysis through the culture's growth. The high sensitivity of nano-DESI allowed the identification of glycolipids not previously reported by using conventional cell extraction methods. Using the spatial profiling capability of nano-DESI, it was found that most of the lipids and metabolites were located on the colony while sucrose and glucosyl were more present in the agar with the gradients of these compounds dependent upon the age of the colony.

CONCLUSIONS

A suite of emerging techniques are poised to provide new data streams for interpreting C migration into and through a soil. By enabling spatially resolved isotope (¹³C) analysis, LA-IRMS offers a method for tracking isotopically labeled substrates into a soil and can identify specific locations where these substrates accumulate or are most rapidly consumed. LA-AMS offers high-throughput, spatially resolved (~2 μm) identification of classes of organic compounds within a soil. This technique can be coupled with LA-IRMS to identify key organics present in sections of a soil showing high ¹³C label accumulation and determine the degree to which the added labeled compound is being chemically modified in this location. Finally, by offering detailed chemical identification of soluble organics, nano-DESI can offer more detailed chemical identification and help identify specific chemical transformations or compound migration in a soil. It is clear from the results of the use of nano-DESI for the determination of chemical gradients produced by microbial communities on agar, as well as the identification of chemical species previously unreported as metabolites, that nano-DESI is a powerful tool with great potential for spatial determination of metabolites of microbes, fungi, roots, and other biological sources in soil.

Taken together, these three methods provide a platform for identifying substrate localization in a soil and, through chemical identification, for tracking the recalcitrance or

reaction products of applied organics within these highly resolved locations.

ACKNOWLEDGMENT

A portion of the research was performed using EMSL, a DOE Office of Science User Facility sponsored by the Office of Biological and Environmental Research and located at Pacific Northwest National Laboratory.

Soil Carbon: Farming and Economic Aspects

Bruce A. McCarl

Agricultural Economics, Texas A&M University, College Station, Texas, U.S.A.

Abstract

A discussion is presented on key issues that will determine whether farming for sale of carbon will ever be an economic proposition. These include the needed market developments that would allow soil carbon to sell, the drawbacks of saturation, and their most likely associated market discounts, market rules, transaction costs, the influence of the biofuel boom, risk, and the potential to bridge to a lower-emission future.

INTRODUCTION

The last years have shown growing interest in soil carbon sequestration. However, soil carbon sequestration is not a significant income source outside of select niche markets [e.g., under the Chicago Climate Exchange (CCX) or the Climate Trust].^[1] This entry reviews the prospects and some obstacles from an economic perspective covering:

- Greenhouse gas (GHG) emission restrictions and the context for making money
- Saturation/new equilibrium and volatility
- Fungibility and market discounts
- Rules and early actor risk
- Soil carbon as a bridge to the future
- Transaction costs, monitoring, and verification
- Signals that are changing farming
- Risk and the no-till panacea

GHG EMISSION RESTRICTIONS AND MONEY

The Intergovernmental Panel on Climate Change^[2] Fourth Assessment Report indicated a high degree of certainty that anthropogenic GHG emissions are contributing to climate change. Furthermore, this report also indicates that climate change is risky and suggests that society reduces GHG emissions. Soil carbon comes into this picture in which carbon dioxide (CO₂), the primary GHG, is released when the soil is disturbed, while carbon content of soil increases (carbon is sequestered) when disturbance is reduced ultimately drawing carbon from the atmosphere. Thus, altering agricultural soil management so as to reduce disturbance generates a net reduction in atmospheric GHGs. This is why there is potential for farming and selling soil carbon.

Market trading is another aspect of soil carbon farming. Economists began suggesting pollution emission rights trading in the late 1960s,^[3,4] allowing firms for which emission reduction is expensive to buy reduction credits from

firms that could reduce more cheaply. This was implemented in the sulfur dioxide trading market where power plants for which sulfur reductions were expensive could buy from other firms in an electronic trading market.^[5] Carbon offers such possibilities. The vast bulk of U.S. emissions come from coal-fired power plants and petroleum use.^[6] Emission reductions in energy use can be very costly raising the issue of whether a market could arise where firms needing offsets could buy from cheaper sources. Agriculture is one potential source. Several estimates indicate that substantial agricultural soil carbon could arise for prices below U.S. \$25 per ton (e.g., McCarl and Schneider^[7] and Antle et al.^[8]). On the other hand, anecdotal estimates of carbon capture and geologic storage of coal power plant emissions are above U.S. \$200 per ton, showing an income earning potential from farming soil carbon.

However, while market trading and GHG regulation are widely discussed, a market will only emerge if we have emission limits. The Kyoto Protocol would have imposed binding emission limits and started a market, but the U.S. Government declined the participation. Instead, in the United States, there is a voluntary “Clear Skies Initiative”^[9] that aims to reduce emission intensity but does not contain features that start a trading program. There are some regional or experimental trading programs. For example, there is voluntarily trading under the CCX and some contemporary or emerging regional binding emissions, which is limited in places like Oregon, California, and the Northeast. However, these are niche markets in which some but not all are covered. Furthermore, U.S. prices have been small being around U.S. \$1–4 per ton CO₂, but European prices have been higher in the vicinity of U.S. \$30. Widespread trading will not occur until some national GHG emission limit is imposed and trading rules developed that permit entry of agricultural soil carbon. (A development that has not really arisen in the Kyoto-based trading in the rest of the world.) Prices may be much higher with projected prices under some atmospheric GHG stabilization schemes being well up into the multiple U.S. \$100s.

SOME ISSUES

Saturation/New Equilibrium and Volatility

Soil carbon is subject to a physical capacity constraint, given a land use as well covered by West and Six^[10] and likely elsewhere in this encyclopedia. When soil disturbance is reduced, then the contribution of carbon to the soil or the destruction of soil carbon is limited through oxidation. Simultaneously, the rate of decomposition starts to increase. When these items equilibrate, a maximum soil capacity is reached and more can be attained only by augmenting the net addition or reducing decomposition by other actions. West and Post^[11] showed that the sequestration from tillage changes may persist for only 10–15 years. Furthermore, reverting to an increased degree of disturbance would rapidly release the carbon, leading soil carbon to be commonly called as volatile or impermanent. The permanence of sequestered carbon has been a major factor in its lack of entry in the international Kyoto trading system.

This approach to equilibrium/saturation has implications for the value of soil carbon and for future farmer options. Farmers must reduce disturbance to get paid but may only be paid while accumulation occurs. In turn, they could not revert to traditional practices without releasing the carbon. This implies a reduced price for carbon if a permanent agreement to maintain reduced disturbance is not negotiated. West and Post^[11] showed that this occurs at a rate of about ¼ ton per acre or a total of around 4 tons over 15 years. Valuing this at the U.S. CO₂ price of U.S. \$4 per ton (about U.S. \$14.70 per ton carbon) implies that the permanent income potential is about U.S. \$60 per acre, while the seven times higher European price yields about U.S. \$420 per acre, either of which may not be large enough for a farmer to permanently commit to changes in disturbance regime. Additionally, Kim, McCarl, and Murray^[12] showed that if farmers are to be paid to maintain the carbon beyond the time it ceases to accumulate or if they lease it for say 20 years, then they are allowed to change practices that the value and returns per acre would be discounted by ½ to 2/3.

Rules, Land Use History, and Early Actor Risk

In reciting a list of possible obstacles and reflecting over conversations with farmers, timing is a practical concern. The Kyoto Protocol has an “additionality” clause saying that the only offsets that should be paid for are those which were stimulated by the market. Numerous farmers have been using reduced disturbance tillage methods for some time, and they often argue that they should be compensated for being good actors. However, strict adherence to additionality would only have tillage changes stimulated by the carbon program being eligible for payment. When a market comes into existence, then it is highly likely that disturbance changes after a certain date are the only ones that

will be paid for; so incentives to adopt are not strong, and in fact, the perverse incentive exists to diminish soil carbon holdings when a market looms on the horizon. Thus, there is a disincentive to farming soil carbon. Furthermore, under the above saturation discussion, the time one is or has been in the regime may be a key factor in payment amount and duration.

Soil Carbon as Part of a Response Agenda

While permanence arguments have been detrimental to opportunities for marketing soil carbon, there are encouraging factors. By no means in a future trading world will soil carbon be dominant. To reduce GHG concentrations, society must reduce emissions from coal-fired power plant and petroleum consumption since they compose roughly 85% of the emissions.^[6] While there are possible ways to do this, they take time to develop and require turnover of capital and the vehicle fleet. Farming soil carbon is something we can do bridging to a lower-emission future.

Transaction Costs, Monitoring, and Verification

Monitoring and verification have been widely discussed as potential impediments to soil carbon sales. Certainly, there is a need to assure that the carbon is accumulating or remaining in place, and thus, there will be a measurement and monitoring cost. Mooney et al.^[13] argued that the cost will be low in the few dollars per ton range. Reportedly, implementation of this is an obstacle in the European model.

In addition, there is a question of contract size. Minimum exchange contracts can be large, i.e., 10,000 tons CO₂, which amounts to at the CCX rating of ½ ton CO₂ per acre per year to the tillage change induced carbon on 20,000 acres or given average farm size of 500 acres, the results from 40 operations, and in a developing country with farm size of a hectare, this would be 8000 operations. This implies the need for a broker as occurring under CCX with Iowa Farm Bureau. Crop insurance agents who pull together groups of farmers typically retain 25% of the premiums they collect, while real estate agents get 6–7%. This portends a substantial price gap between market prices and what farmers receive, further reducing the income opportunities.

Signals That are Changing Farming

While we commonly discuss soil carbon as an option, there are some trends that may be limiting its potential for the future. Fundamentally, this involves the implications of rising energy prices and the biofuel boom. Petroleum prices have risen substantially. This has increased the incentives for farmers to both reduce energy use and produce biofuel feedstocks. Intensive tillage uses substantially more energy than reduced forms, and a substantial increase in reduced

tillage is being observed potentially reducing the likely future tillage change response in a carbon market.

Additionally, the biofuel boom has raised commodity prices and land values and is likely to stay for some time. This provides great incentives to increase land disturbance, e.g., deforesting or converting grasslands into farming, both reducing sequestration. It also limits the potential response to a carbon market.

Risk and the No-Till Panacea

Practical farming considerations also enter into the farming soil carbon picture. Bennett,^[14] in commenting on a paper a number of years ago, alluded to the risk introduced by long-term no-till contracts under the possibility that factors like weed resistance to common herbicides. Furthermore, the work done by Klemme^[15] implies that there are obstacles involved that are limiting reduced tillage adoption.

SUMMARY AND CONCLUSIONS

Whether, and to what extent, carbon will be profitably farmed in agricultural soils will depend on the issues of practical economics and policy design. In some cases, carbon can be enhanced through small alterations in land uses, perhaps to the benefit of all. In other cases, incentives or GHG prices may simply be insufficient to stimulate changes in land use practices. In general, the establishment of a carbon trading market should provide additional economic opportunities for landholders and rural communities. The big questions are as follows:

- Will agricultural soils be approved as a saleable GHG offset with workable rules defined?
- Will the incentives be large enough so that landowners will adopt appropriate practices in their own best interests?
- Can an emissions trading program be designed so the carbon that is paid for remains sequestered for as long as needed?

Soil Conservation: Incentives

David Sanders

World Association of Soil and Water Conservation, Bristol, U.K.

Abstract

Soil degradation is one of the most widespread and serious environmental problems faced by humanity, and millions of dollars are being spent annually on soil conservation programs. Some of these programs are succeeding, but generally progress has been far too slow. As a result, a variety of incentives are being used to encourage land users to adopt soil conservation measures.

TYPES OF INCENTIVES

There are many types of incentives, but they can be divided into two broad categories: direct and indirect.^[1] Direct incentives can be provided in the form of wages, grants, subsidies, and loans, or in kind through the provision of food aid, agricultural implements, livestock, trees, seeds, etc., or in a combination of the two. Indirect incentives include fiscal and legislative measures such as tax incentives, guaranteed inputs and input prices, and land tenure arrangements. They include services such as extension services, technical assistance, the use of agricultural equipment, marketing, storage, education, and training. They also include social services, community organization, and the decentralization of decision-making. Of the two, indirect incentives are by far the more important. This particularly applies to land tenure rights, markets and prices, and the decentralization of decision-making.

Equally important are disincentives. Like incentives, disincentives come in many forms, varying from cash or in kind payments to tax disincentives and legal measures.

In the end, the way a land user reacts to soil degradation and soil conservation programs is most likely to be the result of weighing up all the different incentives and disincentives that may be available or in force at the time.

WHEN SHOULD INCENTIVES BE USED?

The effects of land degradation fall within two broad categories: on-site (or on-farm) and off-site (or off-farm). These can be broken down again into the following four categories, depending on whether the preventive measures needed are perceived by those involved to be cost-effective ("economic") or not cost-effective ("uneconomic"):

1. Where the problem is on-site and the treatment is economic, i.e., it is perceived by the land user to more than pay for itself, the task is primarily one of extension and

providing the land user with the correct type of information. No other incentive should be needed. For example, it may be possible to solve the problem by helping farmers change their farming practices from, say, clean cultivation to no-tillage, as has been done very effectively in Brazil through demonstrations and extension.^[2]

2. Where the problem is off-site and the treatment is economic, the task is again one of extension and no other incentive is needed. For example, farmers on lower slopes who are suffering from excessive off-site runoff and erosion can be protected if farmers on the higher slopes are shown through extension how to grow more profitable perennial crops that provide better ground cover than the grown annual crops.
3. Where the problem is on-site and the only effective treatment is uneconomic, i.e., not perceived by the land user to be worth doing (e.g., the construction of an expensive terrace system), three possibilities arise as follows:

The land user treats the problem for the public good but contrary to his/her own economic advantage.

The land user is forced to carry out the required measures (regulation).

The land user is subsidized to do what is required through one or more incentives. This last possibility is the situation where indirect and direct incentives are most commonly used. For example, in the 1960s, a large and effective program was launched in Jordan to change the use of steep, rocky land that was eroding. Food aid was provided to farmers in return for building stonewall terraces and planting their land to olive and fruit trees instead of continuing to cultivate it for annual cereal crops.^[3]

4. The most difficult situation arises where the problem manifests itself off-site and the on-site treatment is uneconomic for the land user to implement, e.g., where the cultivation of steep upper slopes of a catchment

leads to flooding and erosion lower down, in some cases some distance away. Here the use of incentives may prove to be essential, not only in the short term but also on a continuing basis.

CAUSES AND CONSTRAINTS

The importance of fully involving the land user in soil conservation programs is generally recognized, but what are not widely appreciated are the constraints under which land users operate.^[1]

There are extrinsic and intrinsic factors that affect all land users and the decisions that they take. Extrinsic factors include such things as the farmer's resources of land, capital, and equipment. The intrinsic factors include awareness, technical understanding, skills, and attitudes to conservation. Distinguishing between these factors is important if the correct incentives are to be selected. Too often, programs concentrate on the intrinsic factors and therefore use incentives in the wrong way; for example, it may be a waste of time to provide training to farmers in some new conservation technology if the real reason that they are not adopting conservation practices is lack of capital or of long-term access to land. This is a mistake frequently made in developing countries. On the other hand, a wealthy land user may respond better to training in improved farming techniques than to being provided with subsidies to undertake conservation measures. Without this understanding, incentives may easily be misdirected.

GENERAL PRINCIPLES FOR THE USE OF INCENTIVES IN SOIL CONSERVATION PROGRAMS

The adoption of agricultural innovations, in general, and in soil conservation in particular, is a complex process. Few farmers are able to adopt even simple technologies, let alone packages of conservation measures, without adjusting their traditional practices and their livelihood strategies. A study^[4] on the use of incentives in soil conservation therefore concluded, among other things, that a necessary condition for adoption is that changes must be profitable to the farmer. But profit by itself may not be sufficient to stimulate the required change. Profit maximization, although an important driving force, is by no means the only motivational force.

It must also be understood that, to be effective, the objective of incentives should be to alter the long-term behavior of the land user, not simply to boost adoption rates to meet project targets. It is all too easy for incentives to turn into wages without the recipients making the link between the incentives and the desired conservation work. Far too often, incentive schemes, such as food-for-work

programs, turn into work-for-food programs, without altering the land users' behavioral pattern.

Essentially, incentives are needed when the adoption of conservation measures is not profitable to the land users. Broadly, they are justified when the adoption of these measures produces benefits that are external to the farm, and the provider of the incentives receives the benefits. If society benefits, there is a case for society paying.

Incentives are not simply justified by low incomes. If the desired conservation measures are profitable to land users, it is most likely that land users will find the way to finance the necessary changes. If they cannot, then it may be necessary to provide enabling incentives, such as cheap credit or improved land rights. Incentives may be necessary to overcome barriers to the adoption of profitable conservation measures. Experience demonstrates that incentives may be justified for both rich and poor land users where society clearly stands to gain.

Incentives may also be justified on a continuing basis. Numerous examples exist of projects failing after incentives were withdrawn. In these cases, the land users obviously did not consider the conservation practices profitable without the incentives. But if society derives adequate benefits from the conservation activities, then there is a case for the incentives to be continued indefinitely. It may be necessary, and only fair, that those who benefit pay the cost.

THE IMPACT OF INCENTIVES

To evaluate the impact of incentives, it is necessary to carefully monitor their use and effects. Unfortunately, this is difficult to do and, in practice, is seldom done. Changes in behavior patterns are often difficult to assess and, as a result, the benefits attributed to the incentives are hard to measure.

It is also difficult to differentiate between the effects of different stimuli to which farmers respond, including external factors such as weather and markets. A crucial issue is whether land users actually desire a change and are prepared to alter their land use and management systems. Unless the change is genuinely desired, the land user will just "take the money and run."

In a study,^[4] it was significant that contributors kept returning to the issue of profitability. In one way or another, they all tended to conclude that soil conservation must be profitable for the land user if it is to be sustained. To some this meant that soil conservation must be profitable in its own right without outside incentives. To others it meant that outside incentives must be provided as long as the conservation activity was not profitable by itself. But most agreed that, when the measures are profitable to the land user, they are likely to be adopted and maintained. That is, using incentives to make projects profitable contributes to their success. And, importantly, the sustainability of soil

conservation measures depends on their continued profitability, either with or without continued external incentives.

CONCLUSION

It would seem that the most important requirement is the removal of the many disincentives to soil conservation that exist. This is likely to be very difficult to achieve. Many government policies are designed to overcome other problems, such as inadequate food production and low farm incomes, and these unintentionally contribute to soil degradation. The problem is understandable—governments, and society in general, are inclined to view food production and the welfare of farmers as more important than soil conservation. A major problem faced by those working in soil conservation is to be able to reconcile the multiple objectives of society and not simply to argue for soil conservation for its own sake.

Another challenge is to design sustainable incentives. Soil conservation incentives, particularly in the form of subsidies and technical assistance, tend to be temporary measures. Usually, when these measures are withdrawn, conservation activities also cease. There is a need to build the right types of incentives into the social and economic system for the continuance of soil conservation programs.

In addition to this, the effectiveness of using incentives for soil conservation is constrained by the institutions within which they are applied. The challenge is to devise incentives that work within the particular institutional structure in which the problem exists.

Certainly, there is no single incentive appropriate for every problem.

Soil Conservation: Strategies

Winfried E.H. Blum

Institute of Soil Research, University of Natural Resources and Applied Life Sciences, Vienna, Austria

Abstract

National and international soil conservation strategies are presented, and a new proposal for an Intergovernmental Panel on Land and Soil, in analogy with the Intergovernmental Panel on Climate Change, is presented, aiming at a world soils policy.

INTRODUCTION

Soil conservation means to maintain or to improve the quality of soil for providing goods and services to humankind and the environment. This can best be achieved through participatory approaches involving as many stakeholders as possible. However, successful conservation strategies require a solid scientific and technical background as well as an infrastructure for the transfer of this knowledge to those who need it, e.g., stakeholders and decision makers. Finally, substantial economic resources to sustain soil conservation efforts in the medium and long term are also needed because goodwill alone is not sufficient.

This means that soil conservation is a task for communities at large, on a national and an international basis.

In view of the fact that soils are a limited resource and need to be protected for the benefit of future generations, soil conservation is a task not only for the rural population, particularly farmers and foresters, but also for the whole community. The following deliberations are mainly based on Montanarella.^[1]

NATIONAL SOIL CONSERVATION STRATEGIES

From a historical point of view, several national soil protection strategies and policies have been developed in different countries of the world.

In the United States, the U.S. Soil Conservation Act of 1935 was created, following the catastrophic soil degradation.^[2] The U.S. Soil Conservation and Domestic Allotment Act of 1935 had a long-lasting impact on soil protection strategies and the development of soil conservation actions, both in the United States and at a global scale.^[3] This soil conservation act was later followed by the Food Security Act of 1985 and the Farm Bill, 1996, both indicating that soil conservation in the United States was mainly aiming at combating soil erosion and maintaining soil fertility for agricultural production.

Even with this limited focus, this was a basic step for the development of strategies for soil conservation at national and international levels.

Example of national soil protection strategies is the Federal Soil Protection Act of Germany (1998). This soil protection act is enlarging the focus of soil protection, comprising all the functions of soils, such as natural functions, functions as an archive of natural and cultural history, and functions useful to humans, which means that soil is regarded not only as a basis for the production of biomass but also as a filter, buffer, and transformation substrate, as a habitat for biota and a gene reserve, as well as a physical basis for the development of technical infrastructure and a source of raw materials and geogenic and cultural heritage.

The soil action plan developed by DEFRA^[4] for England goes in the same direction. This first soil action plan for England aims at a comprehensive view on the protection of all soil functions and contains 52 actions on issues ranging from soil management on farms to soils in the planning system, soils and biodiversity, soil contamination, and role of soils in conserving cultural heritage and landscape, and all these actions, taking steps toward more sustainable soil use and protection.

INTERNATIONAL SOIL CONSERVATION STRATEGIES

Increasing concerns about worldwide soil degradation processes, especially in Europe, led to transnational soil conservation strategies, e.g., the Alpine Convention, including eight states with alpine environments in Central Europe, setting legal and administrative measures for the protection of soils, by applying the precautionary principle.

Step forward in international soil protection is the European Union (EU) Thematic Strategy for Soil Protection,^[5] which is based on the recognition of the multifunctionality of soils, in which soils are no longer considered

only as construction surfaces or dumping sites or means for agricultural production, but as a fundamental environmental compartment, similar to air and water, performing vital ecological, social, and economic services for European citizens, including filtering and buffering contaminants, producing clean drinking water, and having a pool of biodiversity, a source of raw materials, a sink of atmospheric carbon dioxide, and an archive of cultural heritage.

Besides these regional policies, global policies aim at strategies for soil conservation, such as the World Soil Charter and the World Soils Policy, and several UN conventions, such as the 1992 Framework Convention on Climate Change, the 1992 Convention on Biological Diversity, and the 1994 Convention to Combat Desertification. However, the strategies behind these global conventions are not strong enough to produce results in achieving global soil protection.

This led to new initiatives in Europe, to create an Intergovernmental Panel on Land and Soil (IPLS), in analogy with the Intergovernmental Panel on Climate Change (IPCC) of the Climate Change Convention. The IPLS should give scientific advice to the public, like the IPCC, and would have the following functions:^[6]

1. To serve as a clearing house for ongoing and periodic assessment of global land and soil degradation
2. To assess and synthesize globally the scientific, technical, and socioeconomic information relevant for the understanding of the risk of human-induced land and soil quality change
3. To address the variety of land use and soil management issues, including desertification as related to environmentally sustainable development
4. To stimulate and involve the scientific community to advance and develop the science of soils in sustainable land use

5. To assist actively national, regional, and global decision makers in developing strategies to assess, monitor, and mitigate negative impacts of land and soil use

CONCLUSION

From these national and international strategies, it becomes clear that a nested system of soil conservation strategies on a worldwide level is needed. The basis of this has to be developed by policy-relevant soil information in order to make knowledge-based decisions. Unfortunately, there is a lack of sufficient data about soils in many parts of the world, including Europe.

The further development of the EU Thematic Strategy for Soil Protection will allow the exploration of new methods for international cooperation in this field.

Soil Conservation: U.S. Historical Perspective

Dana D. York

Watershed and Landscape Programs Division, Natural Resources Conservation Service, U.S. Department of Agriculture (USDA-NRCS), Washington, District of Columbia, U.S.A.

Abstract

In the United States, Americans generally accept abundant agricultural production and environmental quality as compatible national goals—but it has not always been this way. This attitudinal shift is one facet of the legacy of the Natural Resources Conservation Service (NRCS), a U.S. Department of Agriculture agency established in 1935 as the Soil Conservation Service. This entry explores the agency's creation and the enduring influence of its founding chief, soil scientist Hugh Hammond Bennett. It examines the rise of soil and water conservation districts and their continuing role in helping NRCS to deliver conservation technical and financial assistance to the nation's farmers and ranchers. The achievements of this partnership are reviewed, and the work of Bennett's heirs in addressing modern challenges to conservation agriculture is discussed, underscoring the validity of his advocacy for an ongoing program of soil and water conservation on working lands.

INTRODUCTION

As the U.S. Department of Agriculture (USDA) Natural Resources Conservation Service (NRCS) celebrates its 75th anniversary in 2010, it is useful to reflect on the agency's origins, its legacy in ensuring both productive agricultural lands and a healthy environment, and its ongoing role in helping farmers and ranchers to meet their stewardship goals and address modern conservation challenges, including climate change.

HUGH HAMMOND BENNETT AND THE SOIL CONSERVATION SERVICE

The NRCS, a technical agency of the USDA, celebrates its 75th anniversary in 2010. Although the United States began a national program of soil surveying as early as 1899, it did not formalize its Soil Conservation Service (SCS)—the forerunner of today's NRCS—until the mid-1930s. Its establishment was by then long overdue.

Government policies designed to encourage settlement in the near west and poor land management decisions taken by individual farmers had resulted in severe degradation of the American plains, characterized by terrifying dust storms blowing from Colorado's Front Range to the Atlantic Coast. Drought and wind erosion threatened the nation's agriculture-based economy and citizens' quality of life. Faced with these perils, the distinguished soil scientist Hugh Hammond Bennett advocated “retracing our steps

across the land in an effort to correct past mistakes in the interest of the future.”^[1]

A true visionary, Bennett had been laying groundwork for the agency well in advance of its creation. As a federal manager, he lobbied to stand up soil erosion experiment stations and used the results to develop demonstration projects, including comprehensive conservation plans for participating farms. Some of those original plans are in use, in Wisconsin's Coon Creek Watershed and elsewhere (Fig. 1).

But Bennett knew more had to be done, and on a grander scale. He set off on a nationwide speaking tour and went before the U.S. Congress to ask for additional funding and personnel. Initially, his success was limited. Following several dust storms in the spring of 1935 that so blackened the sky it looked like midnight at midday across the plains, Bennett tried again. This time, with detritus from the storms visible from congressmen's windows, his pleas fell on more receptive ears.^[2] Bennett emerged victorious from the hearings. President Franklin D. Roosevelt signed the Soil Conservation Act into law on April 27, 1935, and Bennett became the first chief of the aptly named SCS.

LOCALLY LED CONSERVATION

Two years later, the first local soil conservation district was formed in North Carolina, which included Bennett's family farm. Its founding was a watershed moment, so

Fig. 1 Chief Hugh H. Bennett, Mrs. Bennett, and regional conservator A.E. McClymonds view conservation work on the Frank Milsna farm, Manske Ridge on the Coon Creek Watershed Demonstration Project in Vernon County, Wisconsin, October 25, 1946.

Source: Photo courtesy of USDA NRCS.

to speak, in the history of soil conservation in the United States, as landowners and the government began to share responsibility for conservation on private lands. Government field offices were also set up and staffed with expertise appropriate to the needs of the county being served.

Bennett was convinced of the soundness of this approach: “In this democracy,” he wrote, “national action to conserve soil must be led by these millions of land users. If they are active and willing participants in such a movement, it will endure; otherwise it will fail.”^[1] He also thought participation in agency programs should be entirely voluntary, which it has been to this day.

He was undoubtedly right about the importance of bringing society and soil science together. There are now nearly 3000 conservation districts nationwide that coordinate federal, state, local, and private assistance to enable landowners to put conservation on the ground. As a result of this insightful construct, delivery of conservation programs is connected from policymakers and funding sources in Washington, DC, all the way to individual farmers and ranchers far from the nation’s capital. Moreover, programs are tailored to meet the specific needs of agricultural producers as well as the community at large, ultimately providing benefits to all citizens.

Seventy-one percent of land in the continental United States is in private hands. That equates to nearly 1.4 billion acres (0.57 billion ha).^[3] Thus, the marriage of local leadership and national objectives has been critically important in effecting lasting change for the environment, whether on a single acre or across a landscape. It has also afforded flexibility in program implementation over the years, as science and technology have advanced, funding has ebbed and flowed, and particular regions or resource concerns have become greater or lesser priorities.

FROM SCS TO NRCS

In 1994, the SCS was renamed the NRCS. The work that began in 1935 emphasizing soil health had by that time grown into a broader family of authorities, programs, and strategies, supporting high-quality, productive soils, clean and abundant water, clean air, and healthy plant and animal communities.

The agency, its partners, and cooperating landowners have made the most of NRCS’s expanding role in working lands conservation. Between 1936 and 2009, these entities have acted in concert to install 15 million miles (24 million km) of terraces; put 129 million acres (52.2 million ha) into contour farming and 425 million acres (172.1 million ha) into conservation cropping systems; preserve, restore, or enhance 9 million acres (3.64 million ha) of wetlands; establish or protect 160 million acres (64.8 million ha) of wildlife habitat; and plant 20 million acres (8.1 million ha) of trees (Fig. 2).^[3]

In just a few years, cooperators have installed over 10,000 manure management facilities and preserved 600,000 acres (242,915 ha) through farm and ranch land easement programs.

In the quarter century between 1982 and 2007, conservation programs have also contributed to a 43% decline in soil erosion on cropland nationwide.^[3]

Since the mid-20th century, NRCS and its survey partners have mapped 2.1 billion acres (0.85 billion ha) of soils (Fig. 3). In 2010, the agency conducts soil surveys and other assessments on the World Wide Web, provides online “energy estimator” management tools, and offers both its plants database and field office technical guides electronically, to name a few e-initiatives.

Maps and tables for more than 2300 soil surveys can also be accessed for free on the Internet (<http://www.nrcs.usda.gov/programs/soilsurvey/>), as can the results of

TECHNICAL AND FINANCIAL ASSISTANCE

Thanks to these and other accomplishments, Americans now generally accept abundant agricultural production and environmental quality as compatible national goals—a significant cultural change from Bennett's day.

For the past few years, symbiosis has been expressed through legislation and appropriations informally referred to as “farm bills.” This legislation expires every 5 to 7 years. The latest version, the “Food, Conservation, and Energy Act of 2008,” runs through 2012 and authorizes the largest ever federal investment in natural resources conservation, totaling \$24 billion over 5 years.^[4] For the most part, the funding and authorities resulting from farm bills have supported abundant production while also increasing the capacity of NRCS to get conservation on the ground.

It is worth noting, however, that conservation technical assistance—what the agency views as “the engine of conservation”—is authorized and funded outside farm bill legislation. While there can be no doubt that farm bill financial incentives for farmers and ranchers facilitate adoption of conservation practices, it is technical assistance that makes them feasible and effective.^[5]

SOIL SCIENTISTS: WALKING IN BENNETT'S FOOTSTEPS

Despite changes over the years, the agency's 21st-century soil scientists continue to walk in Bennett's footsteps. They have routinely been leaders in leveraging technology to serve conservation and are front and center helping agriculture confront the challenges of climate change.

The Rapid Assessment of U.S. Soil Carbon for Climate Change and Conservation Planning, now in its initial stages, is a great example. This effort is designed to gather data on soil carbon stocks for the nation, as influenced by soil, agricultural management, land use, and ecosystem characteristics. These data will be available for input into simulation models for erosion prediction. Furthermore, they will be used as a component of conservation planning activities to enhance soil quality, soil carbon sequestration, and ecosystem services.

HELPING PEOPLE HELP THE LAND

Throughout his life, Bennett continued to champion the importance of soil conservation along with the agency he created and shaped. Soil conservation, he wrote in 1943:

is not just an incidental bit of the mechanics of farming; it becomes part and parcel of the whole business of making a living from the land, and is the only way by which we may have permanently productive land for a permanent agriculture to support a permanent nation.^[6]

His legacy is reflected in the vision statement of NRCS, which calls for conservation actions to promote productive lands and a healthy environment, and in its mission of “helping people help the land.”

CONCLUSION

Given the demands of a growing world population with respect to food and other resources, Bennett's message about the importance of conservation is as relevant today as it was in 1935—and just as vital to ensuring sustainable, permanent agriculture for a permanent nation.

ACKNOWLEDGMENTS

The author would like to recognize the contributions of NRCS National Historian Douglas Helms to the agency's—and her own—understanding of, and respect for, its unique place in American agricultural and conservation history. She would also like to acknowledge the assistance of Mary Elder, NRCS Public Affairs.

Soil Degradation: Global Assessment

Selim Kapur

Departments of Soil Science, Landscape Architecture, and Agricultural Engineering, University of Cukurova, Adana, Turkey

Erhan Akça

Center of Remote Sensing, Adiyaman University, Adiyaman, Turkey

Abstract

Although soil provides food, fiber, and nutrients that are essential for humans, its value is rarely esteemed. Soils throughout human history were continuously mistreated, which led to the fall of civilizations. Agricultural and industrialization activities trigger erosion, salinity, and contamination, all of which cause a loss of soil quality to irrecoverable levels. Contemporary soil resource exhaustion has resulted in severe land degradation in many parts of the world; more than 25% of usable global land is degraded. Thus, combatting land degradation is humanity's major priority for global security.

INTRODUCTION

One of the major challenges that humanity will face in the forthcoming decades is the need to increase food production to cope with the ever-increasing population, which is indeed the greatest threat for food/soil security.^[1] The worldwide loss of 12 million hectares (ha) of agricultural land per year was reflected in the average annual loss up to 38 billion for EU25^[2] in spite of the strict laws for environmental protection enacted there. This is the unpalatable but important indicator of a steady decline in agricultural production and an increase in soil damage, reflecting the “impaired productivity” in a quarter of the world's agricultural land.^[3–5]

BACKGROUND

Soil can degrade without actually eroding. It can lose its nutrients and soil biota and can become damaged by waterlogging and compaction. Erosion is only the most visible part of degradation, where the forces of gravity, water flow, or wind actively remove soil particles.

Rather than taking the classical view that soil degradation was, is, and will remain an ongoing process, mainly found in countries of the developing world, this phenomenon should be seen as a worldwide process that occurs at different scales and different time frames in different regions. The causes of biophysical and chemical soil degradations are enhanced by socioeconomic interventions, which are the main anthropogenic components of this problem, together with agricultural mismanagement, overgrazing, deforestation, overexploitation, and pollution as reiterated by Lal,^[6] UNEP/ISRIC,^[7] Lal,^[8] Eswaran &

Reich,^[9] Eswaran et al.,^[10] Kapur et al.,^[11] and Cangir et al.^[12] as the main reasons for erosion and chemical soil degradation.

Soil degradation, the threat to “soil security,” is ubiquitous across the globe in its various forms and at varying magnitudes, depending on the specific demands of people and the inexorably increasing pressures on land. Europe provides many telling examples of the fragile nature of soil security and the destructive consequences of a wide range of soil degradation processes. Asia, Africa, South America, and North America are not only partly affected by the non-resilient impacts of soil degradation but also experiencing more subtle destruction of soils through political developments, which seek to provide temporary relief and welfare in response to the demands of local populations.

Europe

The major problems concerning the soils of Europe are the loss of such resources owing to erosion, sealing, flooding, large mass movements as well as local and diffuse soil contamination, especially in industrial and urban areas, and soil acidification.^[13,14] Salinity is a minor problem in some parts of Western and Eastern Europe but with severe effects at the northern and western parts of the Caspian Sea (with low salinity)^[15] mainly because of the shift to irrigated agriculture and destruction of the natural vegetation (Fig. 1).

The urbanization and construction of infrastructure at the expense of fertile land are widespread in Europe, particularly in the Benelux countries, France, Germany, and Switzerland, and such effects are most conspicuously destructive along the misused coasts of Spain, France, Italy,

Fig. 1 Soil degradation in Europe.

Source: Adapted from UNEP/ISRIC,^[7] Kobza,^[16] USDA-NRCS,^[17,18] Erol,^[19] Kosmas, Ferrara, et al.,^[20] and Kharin, Tateishi, et al.^[21]

Greece, Turkey, Croatia, and Albania. The drastic increase in the rate of urbanization since the 1980s is expected to follow the Blue Plan, which seeks to create beneficial relationships among populations, natural resources, the main

elements of the environment, and the major sectors of development in the Mediterranean Basin and to work for sustainable development in the Mediterranean region. The very appropriate term “industrial desertification” remains

valid for the once degraded soils of East Europe, under the pressure of mining and heavy industry, as in Ukraine where such lands occupy 3% of the total land area of the country.^[22]

There are three broad zones of “natural” erosion across Europe, including Iceland, as follows: 1) the southern zone (the Mediterranean countries); 2) a northern Loess zone comprising the Baltic States and part of Russia; and 3) the eastern zone of Slovenia, Croatia, Bosnia and Herzegovina, Romania, Bulgaria, Poland, Hungary, Slovakia, the Czech Republic, and Ukraine (Fig. 1). Seasonal rainfalls are responsible for severe erosion owing to overgrazing and the shift from traditional crops. Erosion in Southern Europe is an ancient problem and continues in many places, with marked on-site impacts and with significant decreases in soil productivity as a result of soil thinning. The northern zone of high-quality Loess soils displays moderate effects of erosion with less intense precipitation on saturated soils. Local wind erosion on light textured soils is also responsible for the transportation of agricultural chemicals used in the intensive farming systems of the northern zone to adjacent water bodies, along with eroded sediments. The high erodibility of the soils of the eastern zone is exacerbated by the presence of large state-controlled farms that have introduced intensive agriculture at the expense of a decrease in the natural vegetation. Contaminated sediments are also present in this zone, particularly in the vicinity of former industrial operations/deserts, with high rates of erosion in Ukraine (33% of the total land area) and Russia (57% of the total land area), whose agricultural land has been subjected to strong water and wind erosion ever since the beginning of industrialization.

Localized zones of likely soil contamination through the activities of heavy industry are common in North-western and Central Europe as well as Northern Italy, together with more scattered areas of known and likely soil contamination caused by the intensive use of agricultural chemicals. Sources of contamination are especially abundant in the “hot spots” associated with urban areas and industrial enclaves in the northwestern, southern, and central parts of the continent (Fig. 1). Acidification through the deposition of wind-borne industrial effluents and aerosols has been a long-standing problem for the whole of Europe; however, this is not expected to increase much further, especially in Western Europe, as a result of the successful implementation of emission-control policies.^[3]

The desertification of parts of Europe has been evident for some decades, and the parameters of the problem are becoming clear, with existing emphasis on monitoring of the environmentally sensitive areas^[22,20] on selected sites, seeking quality indicators for 1) soil (particularly organic carbon); 2) vegetation; 3) climate; and 4) human management throughout the Mediterranean basin. Apart from the human factor, these indicators are inherent.

Asia

The most severe aspect of soil degradation on Asian lands has been desertification owing to the historical, climatic, and topographic character of this region as well as the political and population pressures created by the conflicts of the past 500 years or so. Salinization caused by the rapid drop in the level of the Aral Sea and the waterlogging of rangelands in Central Asia owing to the destruction of the vegetation cover by overgrazing and cultivation provide the most striking examples of an extreme version of degradation—desertification caused by misuse of land. Soil salinity, the second colossal threat to the Asian environment, has occurred through the accumulation of soluble salts, mainly deposited from saline irrigation water or through mismanagement of available water resources, as in the drying Aral Sea and the Turan lowlands as well as the deterioration of the oases in Turkmenistan, with excessive abstraction of water in Central Asia (Fig. 2).^[21]

The dry lands of the Middle East have been degrading, since the Sumerian epoch, with excessive irrigation causing severe salinity and erosion-siltation problems,^[21] especially in Iraq, Syria, and Saudi Arabia. Iraq has been unique in the magnitude of the historically recorded build up of salinity levels, with 4.81 million ha saline land, which is 74% of the total arable land surface (i.e., 90% of the land in the southern part of that country). The historical lands of Iran, Pakistan, Afghanistan, India, and China are also subject to ancient and ongoing soil degradation processes, which are subtle in some areas but evident and drastic in others (Fig. 2).

Africa

Africa's primary past and present concern has been the loss of soil security by nutrient depletion, i.e., the decreasing NPK levels (kg ha^{-1}) along with micronutrients in cultivated soils following the exponential growth in population and the resulting starvation and migrations (Fig. 3). The intensification of land use to meet the increased food demands combined with the mismanagement of the land leads to the degradation of the continental soils. This poses the ultimate question of how the appropriate sustainable technologies that will permit increased productivity of soils can be identified. This problem is illustrated by the example of the Sudan, where nutrient depletion has steadily increased through more mechanized land preparation, planting, and threshing without the use of inorganic fertilizers, and legume rotations. Thus, aggregate yields have been falling as it became more difficult to expand the cultivated area without substantial public investments in infrastructure. This decline in yield has occurred at enormous rates in Vertisols of Sudan, with the mean annual sorghum yields decreasing from 1000 to 500 kg ha^{-1} and the wholesale price of sorghum increased 3.7% per month since 2007.^[24] In Burkina Faso, the decreased infiltration and

Fig. 2 Soil degradation in Asia.

Source: Adapted from UNEP/ISRIC,^[7] Erol,^[19] Kosmas, Ferrara, et al.,^[20] and Lowdermilk.^[23]

increased runoff causing erosion are further consequences of repeated cultivation. Thus, the technological measures to be identified for these two African examples must include development of water retention technologies in Burkina Faso, while polyculture/rotations with proper manuring and fertilization for cost-efficient provisions of nitrogen and phosphorus and preferably green manuring are all needed in Sudan to permit the balanced management of soil moisture, nutrients, and organic matter [and to enhance carbon (C) sequestration, a main goal for sustainability based on the earth sciences—to ensure the security of both the soil and global climate].^[24,25]

Central and South America

Africa and Latin America have the highest proportion of degraded agricultural land. Water and wind erosion are the dominant soil degradation processes in Central America and South America and have caused the loss of the topsoil at alarming rates because of the prevailing climatic and topographic conditions. Almost as important is the loss of nutrients from the Amazon basin (Fig. 4).^[26] These effects are mainly attributable to deforestation and overgrazing, the former being responsible for the degradation of 576 million ha out of 1000 million ha potential agricultural land. Another important factor has been the ever-increasing introduction of inappropriate agricultural practices derived from the so-called imported technology, which have not been properly adapted to indigenous land use procedures. The traditional methods of permitting the land to recover naturally have been almost totally abandoned and replaced by unsuitable technological measures designed to maintain production levels (temporarily) and to overcome the loss of soil resilience, thus increasing chemical inputs.

The rapid industrialization/urbanization of the limited land resources in the Caribbean region has been expelling agricultural communities to remote and marginal regions that are at present rich in biodiversity and biomass—a major global C sink. Moreover, large-scale livestock herding of Central America and South America is also a major threat to soil security and has been responsible for degrading 1 million km² of Argentinean, Bolivian, and Paraguayan pasturelands.

North America

The most prominent outcome of soil degradation (or more correctly desertification) in the United States is exemplified by the accelerated dust storm episodes of the 1930s—the Dust Bowl years, marked by the “Black Blizzards,” which were caused by persistent strong winds, droughts, and overuse of the soils. These resulted in the destruction of large tracts of farmland in the South and Central United States. Salinization has become an equally severe problem in the western part of the country (Fig. 5) through the artificial elevation of water tables by extensive irrigation, with associated acute drainage problems. An area of about 10 million ha in the west of United States has been suffering from salinity-related reductions in yields, coupled with very high costs in both the Colorado River basin and the San Joaquin Valley.^[27] Unfortunately, new irrigation technologies, such as the center pivot irrigation system (developed as an alternative to the conventional irrigation systems causing the salinity problems), have caused a decline of the water-table levels in areas north of Lubbock, Texas, by around 30–50 m, leading to a dramatic decrease in the thickness of the well-known Ogallala Aquifer by 11% decrease between 2003 and 2011 only.

Fig. 3 Soil degradation in Africa.
Source: Adapted from UNEP/ISRIC^[7] and Lowdermilk.^[23]

In some areas, this has been followed by ground subsidence, which is an extreme form of soil structure degradation, i.e., loss of the physical integrity of the soil.

Loss of topsoil, as a result of more than 200 years of intensive farming in the United States, is estimated to vary between 25% and 75% and exceeds the upper limit in some parts of the country.^[18,19] The United States provides good examples of the difficulties involved in erosion control,

with its large-scale intensive agriculture—deteriorating soil structure and increasing erosion of its susceptible soils. This problem could be overcome primarily by the strict introduction of the no-till system. No-till areas have increased from 4 million ha in 1989 to 25.3 million ha in 2004, and they are forecast to follow a linear extrapolation until 48 million ha out of the total 81 million ha of cultivated land will be attained.^[28] Conservation farming is

Fig. 4 Soil degradation in Central America and South America.
Source: Adapted from UNEP/ISRIC^[7] and Kharin, Tateishi, et al.^[21]

practiced in only about half of all U.S. agricultural land and on less than half of the country's most erodible cropland. Conservation farmers are encouraged to use only the basic types of organic fertilizers, such as animal and green manure together with compost, mulch farming, improved pasture management, and crop rotation, to conserve soil nutrients.

Canada is a large country where 68 million ha of available land is cultivated, which is only the 7.4% of the

territorial of the country with an average farm size of 450 ha. It is reported that Canada has experienced annual soil losses on the prairies, through wind and water erosions, which are similar to the Asian steppes, amounting, respectively, to 60 and 117 million tons. These annual rates are much higher than the rate of soil formation, resulting in an annual potential grain production loss of 4.6 million tons of wheat. With regard to primary soil salinity, during historic times, the prairies have experienced steady increases

Fig. 5 Soil degradation in North America.

Source: Adapted from UNEP/ISRIC^[7] and Kharin, Tateishi, et al.^[21]

related partially to increasing groundwater levels. Major problems of secondary salinity are estimated to affect 2.2 million ha of land in Alberta, Saskatchewan, and parts of Manitoba, with an immense economic impact each year.

Australia

The Australian agricultural/soil resource base has been endangered, as the “business-as-usual” concept was adopted on the continent to achieve temporary economic betterment. The identification of different types of soil degradation in Australia reveals that erosion has been the main component, primarily via dust storms, which are a serious problem, especially where cropping practices do not include the retention of cover and minimum tillage methods. Water erosion effects are also particularly severe in areas of summer rainfall and topographic extremities (Fig. 6). Although water is a scarce resource in Australia, about 14 million tons of soil is lost in Australia by water erosion. Remedial actions for this include the well-known measures of maintaining adequate cover and changing prevailing attitudes toward stock management, storage feed, redesign of watering sites, and management of riparian areas.

Part of the excess salinity in Australia is of primary origin and was retained in the subsoil by trees, which have been cleared to create soil surfaces for cropping and pastures, allowing the penetration of water to the saline subsoil, then followed by abstraction from the water table, thus leading to the ultimate disaster. About 30% of Australia’s agricultural land is sodic, creating poor physical conditions and impeded productivity. This problem can only be alleviated by massive revegetation programs and by taking extra care of the water table and plant cover. Despite the introduction of costly conventional measures for reclamation, salinity levels continue to increase across Australia in the dry and irrigated soils. The dryland salinity in the continent affects about 5 million ha of farmland and is expanding at a rate of 3–5% per year.^[29]

The retardation of organic matter levels also requires remediation measures, with economically justified fertilizer use strategies to be utilized throughout the continent. Moreover, overgrazing has resulted in the impoverishment of plant communities and loss of habitats as well as the decline in the chemical fertility of the soil by progressive depletion of organic matter in the topsoil, followed by deterioration in the soil structure.

Acidification caused by legume-based mixed farming plus use of ammonia-based fertilizers threatens 55 million ha of Australian land. Liming seems to be the most effective remedy, but is costly, does not lead to rapid recovery, and is impractical for subsoil acidity. Thus, the precise remedies are yet to be developed for the conditions on this continent, utilizing careful, long-term monitoring and the experience of farmers to devise specific treatment and conservation procedures.

Fig. 6 Soil degradation in Australia.

CONCLUSION

The state of soil degradation and its remedies as a multi-function–multi-impact approach have been identified through a Driving Force–Pressure–State–Impact–Response matrix by the European Environmental Agency^[2] (Fig. 7), leading to sustainable land management (SLM)^[30–32] measures to be taken for the future. SLM is concerned with more soil-friendly farming practices that minimize the erosion potential of soils, together with the adoption by landholders of property management planning procedures that involve community actions undertaken within several concerted action projects of the European Union, Food and Agriculture

Fig. 7 Driving Force–Pressure–State–Impact–Response framework applied to soil.

Source: Adapted from World Bank.^[30]

Organization, Global Environment Facility, United Nations Environment Programme, International Crops Research Institute for the Semi-Arid Tropics, Canadian International Development Agency, and World Bank.^[33] Moreover, as Smyth and Dumanski^[34] have stated, these combine socioeconomic principles with environmental concerns, so that the production is enhanced, together with the reduction of its level of risk with the protection of natural resources, which would prevent the degradation of soil and water quality to be successfully accepted by the farmer. The methods to be adopted for SLM via community actions include contour farming, terracing, vegetative barriers, and other land use practices amalgamated with indigenous (traditional) technical knowledge (ITK)^[32] as applied to farming and landscape preservation. The impetus to the use of ITK by scientists and local communities in creating new strategies for sustainable resource management was initiated in the United Nations Conference on Environment and Development held in Rio de Janeiro (Brazil) in 1992, and the need for raising awareness and combatting land degradation is man's priority for global social security.

Abstract

Soil enzymes play a key role in the energy transfer through decomposition of soil organic matter and nutrient cycling, and hence play an important role in agriculture. These enzymes catalyze many vital reactions necessary for the life processes of soil microorganisms and also help in stabilization of soil structure. Although microorganisms are the primary source of soil enzymes, plants and animals also contribute to the soil enzyme pool. Soil enzymes respond rapidly to any changes in soil management practices and environmental conditions. Their activities are closely related to physio-chemical and biological properties of the soil. Hence, soil enzymes are used as sensors for soil microbial status, for soil physio-chemical conditions, and for the influence of soil treatments or climatic factors on soil fertility. Understanding the possible roles of different soil enzymes in maintaining soil health can help in the soil health and fertility management, particularly in agricultural ecosystems. In this entry, we describe the major soil enzymes and their role in nutrient cycling, soil fertility, and yield sustainability. The effects of cropping systems, crop management, and nutrient management practices on soil enzyme activities are discussed. We further discuss the reports on the effect of climatic factors like elevated carbon dioxide, temperature, and drought on soil enzymes activities. Advancements in enzyme activity assay tools are also discussed, followed by prospects in the field of soil enzymes. To conclude, soil enzymatic activity is a useful tool for assessing and managing productivity of an ecosystem.

INTRODUCTION

Soil enzymes are the key players in biochemical process of organic matter recycling in the soil system and their activities are closely related to soil organic matter (SOM), soil physical properties, and microbial activity and/or biomass. Depending on their location, enzymes can be extracellular or intracellular. Intracellular enzymes are found in cell's cytoplasm or bound to the cell walls of living and metabolically active cells, viable but non-proliferating cells (such as spores) and dead cells. Extracellular enzymes released into the soil and are "permanently" immobilized on clay and humic colloids via ionic interactions, covalent bonds, hydrogen bonding, entrapment, and other mechanisms.

Soil enzymes are necessary catalysts for decomposition of SOM and nutrient cycling and, strongly influence energy transformation, environmental quality, and agro-nomic productivity. However, mechanical tillage, monoculture, and residues removal adversely impact enzymatic activity and availability of plant nutrients. In general, enzymatic activity decreases with an increase in soil depth. Further, soil enzymes provide early detection of changes in soil health because they respond to soil management changes and environmental factors much

sooner than other soil quality parameters. Moreover, availability of well-documented assays for a large number of soil enzyme activities makes them the preferred tool for assessing soil health. However, it is necessary to understand the relationship between different enzyme pools and biotic and abiotic factors to predict the potential impact of soil management and environmental changes on ecosystem functions and productivity.

MAJOR SOIL ENZYMES AND THEIR FUNCTIONS

Major soil enzymes used as soil function indicators are presented in [Table 1](#). The activities of these soil enzymes can be used for a meaningful assessment of reaction rates for important soil processes, soil productivity, microbial activity, and inhibiting effects of pollutants, etc.^[1]

EFFECT OF AGRO-TECHNIQUES AND CROPPING SYSTEMS ON SOIL ENZYMES

Soil enzymes, being necessary catalysts for organic matter recycling, strongly influence soil fertility and agronomic

Table 1 Major soil enzymes and their functions.

Enzyme	Source	Reaction catalyzed	End product	Soil function indicated	Factors influencing enzyme activity
α -Amylase	Plants, animals, and microorganisms	Starch hydrolysis	Glucose and/or oligosaccharides	C-cycling	Management practices, type of vegetation, environment, and soil types.
β -Amylase	Mainly plants	Starch hydrolysis	Maltose		
Dehydrogenase	Microorganisms	Oxidation of organic compounds	Transfer of H to NAD or NADP (electron transport system)	C-cycling, microbial oxidative activity	Soil water content, temperature, pesticides, trace elements, management practices, pollution, etc.
Endo-1, 4- β -glucanase	Microorganisms, protozoa, and termites	Cellulose endohydrolysis	Oligosaccharides	C-cycling	Temperature, pH, water, O ₂ contents, quality and location of organic matter, mineral elements, and fungicides.
Exo-1, 4- β -glucanase		Cellulose cleavage at ends	Glucose and cellobiose		
β -glucosidase		Cellobiose hydrolysis	Glucose (sugar)		
Phenol oxidase	Plants and microorganisms	Lignin hydrolysis	C compounds (humic substances)	C-cycling	Soil pH, mean annual precipitation and temperature, SOM content, management practices, N enrichment, etc.
Urease	Microorganisms, plants, and some invertebrates	Urea hydrolysis	Ammonia (NH ₃) and CO ₂	N-cycling	Cropping history, organic matter content, soil depth, management practices, heavy metals, temperature, pH, etc.
Alkaline phosphatase	Mainly bacteria	Hydrolysis of esters and anhydrides of phosphoric acid	Phosphate (PO ₄)	P-cycling	Organic matter content, pH, management practices, pollution, crop species, and varieties.
Acid phosphatase	Plants, fungi, and bacteria				
Arylsulfatase	Microorganisms, plants, and animals	Hydrolysis of sulfate esters	Sulfate (SO ₄ ⁻²)	S-cycling	Heavy metal pollution, pH, organic matter content and composition, and availability of organic sulfate esters
Protease	Microorganisms and plants	N mineralization	Plant available N	N-cycling	Humic acid concentration, availability of C and N, etc.
Chitinase	Plants and microorganisms	Degradation and hydrolysis of chitin	Carbohydrates and inorganic nitrogen	C- and N-cycling	Availability of N, soil depth, atmospheric CO ₂ levels, etc.

NAD: nicotinamide adenine dinucleotide, NADP: nicotinamide adenine dinucleotide phosphate.

productivity. Qualitative and quantitative changes in soil enzymes determine the availability of nutrients and crop productivity. Different agricultural practices like tillage, cropping systems, and nutrient management influence the soil enzyme activities, thereby influencing yield sustainability.^[2]

Adverse impacts of mechanical tillage, cropping systems, and residues removal have been observed in soil enzymatic activities and availability of plant nutrients.^[3] Management-induced changes in soil moisture, temperature, and soil organic carbon (SOC) input influence

microbial biomass carbon (MBC), nutrient availability, and SOC turnover.^[4] Plowing disrupts macroaggregates and accentuates mineralization of the labile SOC pool whereas stable aggregation protects SOC and influences SOM turnover and soil fertility.^[5] There is a close relationship between SOC concentration and soil enzyme activities, which is influenced within particular horizons by other factors (i.e., pH, texture, and gleying). As the enzymatic activity decreases with increase in soil depth, management-induced differences are observed more in the surface than in the subsoil.^[6] Thus enzyme activities can be

used to evaluate the degree of alteration of soils in both natural and agroecosystems.

Aon, Cabello et al.^[7] showed that certain enzymatic activities (acid and alkaline phosphatases, dehydrogenase, fluorescein diacetate (FDA) hydrolysis, β -glucosidase, and urease) and groups of bacteria and fungi exhibit strong links independent of season and crop, despite fluctuations shown by the different microbial and biochemical activities along with oxygen (O₂) and carbon dioxide (CO₂) fluxes as a function of time and space. The spatiotemporal pattern of microbial and biochemical activities exhibited an identifiable path: fungal biodiversity increased, microorganisms stratified as a function of depth unlike all enzymatic activities that showed the maximal stratification.

Fertilization exerts a strong influence on soil quality. Organic amendments such as farmyard manure (FYM), plant residues, and compost are known to improve soil physical and chemical properties, increase SOM, urease activity (UA) and acid phosphatase activity, and enhance soil quality. Amending with organic matter and application of balanced fertilizers improve soil biological properties including microbial biomass and enzymatic activities.^[5,8–10]

Optimum and balanced application of plant nutrients significantly increases the dehydrogenase activity (DHA) that is indicative of the oxidative activity of soil microflora, and hence microbial activity. However, DHA may not be a reliable index of microbial activity for soils receiving high nitrogen (N) inputs, as it is adversely affected by N fertilization. Treatments receiving high rate of N either as chemical fertilizers alone or in combination with organics and the N fertilized wheat (*Triticum aestivum*) cropping system have shown high UA.^[9]

Effects on DHA also differ with source of nutrients applied. For instance, the activity is more with organic N sources as compared to mineral N.^[6] Basu, Mahapatra, and Bhadoria^[11] reported that integrated application of organic or industrial wastes, soil ameliorants, and chemical fertilizer could improve the biological properties of an acid lateritic soil and dry matter production of groundnut, intercropped with sabai grass (*Eulaliopsis binata*). Similarly, application of lime or rice husk ash has been reported to improve DHA and alkaline phosphomonoesterase enzymes and decrease acid phosphomonoesterase activity.^[11]

Cropping systems have a definitive bearing on soil enzymatic activity. In general, soils under legume-based systems contain relatively high MBC than those under other systems. Similarly, integrated use of chemical fertilizers and FYM for 3–7 yr increased MBC and microbial activity under jute (*Corchorus capsularis*)–rice–wheat system in some tropical agricultural soils.^[12] In a study conducted in tropical region of Colombia, Vallejo, Roldan, and Dick^[13] observed that silvi pastoral system stimulated soil MBC and enzymatic (β -glucosidase, UA, and alkaline and acid phosphatase) activities and provided more favorable microbial habitat as compared to monoculture pasture.

Monoculture practices cause decrease in soil enzyme activities when compared with legume-based rotations. Reducing the duration of fallow in a fallow–wheat rotation enhanced enzyme activities and accentuated cycling of C and phosphorus (P).^[14] Soil biological properties and DHA are enhanced by management systems, which add biomass C through legume-based rotations, agroforestry systems, or conservation tillage. It is precisely because of its rapid response to management that the DHA is considered a good biological indicator of soil quality.^[9]

The maintenance of SOC is the main factor that favors the microbial activity and the enzyme activity that correlates with the soil microbial biomass. Bonanomi et al.^[15] reported a positive correlation between enzymatic activities and total SOC content. Forest cleaning, cropping, and management practices affect the soil microbial activity and hence the enzyme activity, a fact attributed to less C inputs. Similarly, the intensively managed soils exhibit decrease in microbial activity in comparison to well-managed pastures.^[16] In high-input management regime soils, a drastic reduction in microbial biomass and fungal mycelium has been observed. The positive correlation between organic C content and both microbial biomass and fungal mycelium suggested that a reduction in the available organic C induced a decrease in the decomposer biomass.^[15] Besides, several other factors having influence on soil enzyme activity are summarized in Table 2.

SOIL ENZYMES AND YIELD SUSTAINABILITY

Many studies have reported significant correlation between soil enzymatic activity and plant yield, whereas some studies show no close relationship. For example, mean grain yields of different crops across rainfed production systems were positively correlated with DHA, arylsulfatase activity (ASA), and UA in soil.^[10] Grain yields of groundnut–finger millet, finger millet mono cropping, winter sorghum, soybean, and upland rice were significantly and positively correlated with DHA, ASA, and UA activities whereas groundnut mono cropping and pearl millet with three enzymes were not.^[18] The probable reason was that the latter two cropping systems were practiced under semiarid conditions with relatively low rainfall (~500 mm annually) and high mean annual temperatures as compared with the other five systems. The sustainable yield index was also positively correlated with all the three enzymes in all production systems except in case of soybean (no correlation with ASA and DHA). However, under irrigated maize–wheat–cowpea system, Manjaiah and Singh^[19] reported significant correlation between yields and all the soil enzymes studied. Similarly, using linear regression models, Lopes, de Sousa et al.^[27] interpreted the enzymatic activities (cellulase, β -glucosidase, acid phosphatase, and ASA) as a function of the relative cumulative yields of corn and soybean. The plant productivity is under the influence of many

Table 2 Response of soil enzyme activity under different ecosystems/practices.

Ecosystem/Practice	Enzymes of C-cycling	Phosphatase	Dehydrogenase	Enzymes N-cycling	Total organic carbon	References
Forest vs. pasture vs. agricultural	Highest (β -glucosidase) in forest, lowest in agricultural soil	Highest (alkaline phosphatase) in forest, lowest in agricultural soil	—	Highest (urease) in pasture lowest in agricultural soil	Highest in forest	Kizilkaya and Dengiz ^[20]
Conservational vs. conventional tillage	High (β -glucosidase)	High	High	High urease and protease	High	Roldan et al. ^[21]
Organic residue with RDF (maize residue in rice and wheat cultivation)	High (invertase)	High alkaline phosphatase	High	High urease and protease	—	Tao et al. ^[17]
Organic vs. unamanded (in bell pepper)	High (β -glucosidase)	High acid phosphatase	High	High urease	High	Gopinath et al. ^[22]
Rehabilitated (stabilized soils (over a 50 yr period) on moving sand dunes	High (α - and β -glucosidase)	High	High	High protease	High	Zhang et al. ^[23]
Degraded vs. native vegetation	Low (cellulose)	—	Low	—	Low	Araújo et al. ^[24]
Mined (coal mine soil vs. forest soil)	—	—	Low	—	Low	Kumar et al. ^[25]
Polluted	—	Low acid and alkaline phosphatase	—	—	—	Ohiri et al. ^[26]

factors like soil quality, plant genotype, biotic and abiotic stresses, etc. Further, in managed ecosystems, many other factors (external inputs) may influence the relationship between enzyme activity and plant productivity.

MEASUREMENT OF SOIL ENZYMES ACTIVITIES

Enzymatic activities have been measured by detecting degradation of the target substrates and the generation of the products. A variety of methods depending on the mode of detection (spectrophotometry, fluorescence, and radiolabeling), the reaction substrates, and conditions (temperature, use of buffers, time of reaction, etc.) have been used for measuring the enzyme activities in soils. The enzymatic assay can be direct where substrate is added to the soil system and the product formed is quantified or indirect where enzyme is extracted from the soil and assayed afterward. Extractability of the soil enzymes is a drawback in an indirect method as a significant portion of the soil enzymes is bound to soil components and is not extracted completely. Assays based on substrate-induced respiration have been developed to measure enzyme activity. In this method, a substrate is added to soil, and production of CO₂ or consumption of O₂ is measured. Simultaneous measurement of substrate-induced respiration of numerous substrates has been made possible by multiwell plate system.

Advances in molecular biology has opened up opportunities to develop genomic, transcriptomic, and proteomic approaches to estimate the potential of a complex microbial community to produce a specific enzyme, expression of enzyme-coding genes, and presence of a specific enzyme in an environment.^[28,29] The abundance of enzyme-encoding genes or transcribed [messenger RNA (mRNA)] sequences has been used for assessing enzyme activity. However, there are many challenges associated with detection and quantification of enzyme-coding genes. For instance, many of the genes are not well conserved and many enzymes have alternate forms with the same function. Use of multiple primers or degenerate primers can help to detect the different forms of a gene. The detection of abundance of an enzyme-coding gene indicates only the potential function and not the expression level of the gene in an environment. The expression of a gene can be indicated by the presence of an mRNA transcript that correlates more closely with enzyme production rates than gene copies. However, the persistence and turnover of the enzyme have to be considered while interpreting the enzyme activity by gene expression.^[29] With the development of GeoChip, thousands of functional genes can be targeted together, thereby covering a significant portion of enzyme-catalyzed processes. Besides, quantitative polymerase chain reaction of gene sequences or mRNA transcripts can be used for quantification of enzyme-encoding genes. However, it is

an indirect method of assessing enzyme activity, and as the genes encoding inactive molecules are also included, accurate assessment of enzyme activity is difficult. *In situ* zymography technique for 2-D distribution of enzyme activities in soil has been applied to map and quantify protease and amylase activity in the rhizosphere of lupine (*Lupinus polyphyllus*).^[30] In this method, thin gels with embedded substrates are incubated with the enzyme and the substrate remaining in the gel after incubation is quantified using calibration curves and digital image analysis. Thus, with some considerations, different assay methods can provide reliable information on the soil enzymes profile.

SOIL ENZYMES AND CLIMATE CHANGE

Increasing atmospheric concentrations of CO₂ and other greenhouse gases is causing global warming and altered precipitation patterns. The activities of soil enzymes are influenced by abiotic (e.g., temperature, water potential, and pH) and biotic (e.g., enzyme synthesis and secretion) factors. Climate change-induced extreme weather events are impacting agriculture and hence can affect quality and quantity of soil enzymatic activity. These changes will have important consequences for ecosystem functions such as decomposition, nutrient cycling, and plant-microbe interactions, which will ultimately affect productivity and net C balance. The impacts of climate change on microbes and their extracellular enzymes, although of profound importance, are not well understood, but may be predicted, assessed, and managed.^[29,31]

Growing concern about the potential consequences of climate change on soil processes, coupled with a desire to develop methods of improving C sequestration, has stimulated experimental research, modeling, and theorizing.^[29] Microbial enzyme activities are responsible for the synthesis as well as decomposition of SOM, though the rate of synthesis and decomposition processes determines net C balance in the soil.

Elevated atmospheric concentrations of CO₂ may affect soil microbial communities directly and indirectly. Increased plant rhizodeposition, water use efficiency, and accelerated nutrient uptake under elevated atmospheric CO₂ strongly affect microbial activities. Increased activities of oxidative enzymes (degrade resistant SOM) and enzymes involved in N and P mineralization (chitinases, peptidases, and phosphatases) have been observed in response to elevated CO₂, whereas no response or decreased activity observed for C-degrading enzymes indicating the influence of elevated CO₂ on microbial responses associated with C-, N-, and P-cycling.^[29,32] Thus, the labile substrate additions through increased rhizodeposition can stimulate the decomposition of more resistant SOM due to extracellular enzymatic activity. However, the effects may vary in different ecosystems. For example, in peatlands where substrate is not a limiting

factor, low O₂ availability and low pH restrict activities of oxidative enzymes (phenol oxidase and peroxidase) lead to accumulation of phenols that inhibit hydrolytic activity and microbial substrate utilization. This, in turn, contributes to organic matter accumulation. On the other hand, in the substrate limited arid systems, photodegradation of surface litter reduces soil input, low redox potentials of phenols due to alkaline pH, and active oxidative enzymes due to arid conditions lead to increased decomposition of recalcitrant C compounds.^[29]

Available scanty literature suggests that warming effects could be either positive or negative depending on the nature and kinetics of the target enzyme being assayed. It has been observed that the temperature sensitivity of extracellular enzymes changes seasonally. A study in Mediterranean indicated that soil UA and β -glucosidase activity were positively correlated with soil temperatures in winter and negatively in summer. Warming increased soil enzyme activities in winter (when soil moisture was highest) and in spring (coinciding with the greatest biological activity).^[33] Steinweg, Dukes et al.^[31] observed difference among seasons and treatments in mass-specific enzyme activity indicating that enzyme production was not directly controlled by size and activity of microbial biomass. Mass-specific enzyme activity increased with increase in temperature from low to medium warming and declined at higher temperature, suggesting that enzyme production increased with temperature or turnover rate decreased. In general, enzyme activity increases with temperature (up to some optimum) and so at least theoretically the rate of enzymatically catalyzed reactions will increase due to warming, assuming that enzyme pool sizes remain constant.^[29] On the other hand, warming may also increase enzyme denaturation rates and the activity of extracellular proteases which would counteract any changes in enzyme pool sizes. In a study by Gong, Zhang et al.,^[34] warming enhanced phosphatase activity (35.8%) but inhibited the cellulase activity (30%) in grassland ecosystem. In addition, warming caused reduction in soil C (7.2%) and available P (20.5%). Further, significant interactive effects of warming and N addition on soil enzyme activity indicated that global change may alter nutrient cycling by influencing soil enzyme activity.

Changing seasonal precipitation patterns may increase drying/wetting events in the soil. The diffusion of enzymes, substrates, and reaction products in the soil depend on soil texture and moisture. Under low moisture conditions, *in situ* enzyme activities are low although in some microsites where solute concentration increases within pore spaces may exhibit high activity. Prolonged droughts are likely to decrease enzyme production resulting in lower measured activities. However, slower enzyme turnover in dry soils, along with continuous production (even at low rates) could lead to increase in pool size during a drought.^[29,31] Rewetting leads to increased availability of organic matter (due to cell lysis and disruption of soil aggregates) which may

result in a pulse of microbial biomass turnover thus causing a temporary increase in extracellular enzyme activities. On the other hand, decreased microbial biomass could lead to a decrease in enzyme production and a decline in the relative abundance of different types of enzymes. Whereas under prolonged precipitation, enhanced plant growth and rhizodeposition result in increased enzymatic activities.

The net effect on enzyme activity depends on how both enzyme production and turnover are affected by changes in climatic conditions. The complexity of interactions between different climatic factors and soil properties makes it difficult to pinpoint the effect of a single abiotic factor on a particular soil enzyme.^[31] As soil enzymes play important role in nutrient cycling, all the climate change studies must consider soil enzymes activities as important parameter while quantifying the outcomes of climate change.

SOIL FAUNA IN RELATION TO SOIL ENZYME ACTIVITY

The role of soil fauna as indicators of soil health is gaining importance. This group comprises the invertebrate community that plays roles in supplying pretransformed organic material to the microorganisms after fragmentation, resulting from their feeding process. Besides increasing the contact surface, the fauna helps in bioturbation of litter and also contributes to soil enzymes. The most representative organisms normally studied as indicators of soil health belong to the mesofauna, which lives in soil macropores and spaces in the soil–litter interface, feeding on fungal hyphae and organic matter, and thus taking part in nutrient cycling and soil aggregation. The macrofauna includes bigger soil organisms which sometimes are active in soil functioning. Increasing number of studies on effects of soil fauna on soil health parameters have been reported with some studies emphasizing on the influence of soil fauna on soil enzymes.^[16]

An increase in invertase, protease (during rice and wheat cultivation), and alkaline phosphatase (during rice cultivation) activity was observed in the presence of earthworms when maize was used as residue whereas no change in DHA observed in the presence of earthworms. Additionally, the five enzyme activities in earthworm casts were significantly higher than those in the surrounding soil, especially DHA and invertase activity. This result suggests that the increased degradation of maize residues by earthworms enhanced substrate concentrations in soil resulting in high microbial activity.^[17] The functional role of soil fauna also varies depending on feeding habit and the physico-chemical properties of plant litter. Mukhopadhyay, Roy, and Joy^[35] compared the feeding impact of *Anoplo-desmus saussurei* (Humbert) feeding on semiliquid portions and *Porcellio laevis* (Latraeille) feeding by scrapping soft tissues, on litter breakdown and soil enzyme activities on decomposing leaf litter of two forest tree species, *Cassia siamea* (litter high in soluble carbohydrates,

cellulose, and hemicelluloses) and *Shorea robusta* (litter high in polyphenols, tannin, and lignin) in microcosms. Feeding by *A. saussurei* and *P. laevis* caused significant weight loss and decline of the main chemical constituents in *C. siamea* litter, whereas the weight loss was much less in *S. robusta*. Soil enzyme activities were influenced by litter quality, with *C. siamea* litter exhibiting higher amylase, cellulase, and invertase activities than *S. robusta*. Soil enzyme activities were also influenced by the presence of detritivores. Amylase activity increased in the presence of both arthropods in *C. siamea* and *S. robusta* litters. Cellulase activity was enhanced only by *A. saussurei* in both litters, whereas both detritivore species contributed to higher invertase activity in *S. robusta* litter. Further the positive impact of *A. saussurei* was greater than that of *P. laevis* for all the enzymes in *S. robusta* litter. The results indicated a direct and species-specific comminuting effect of detritivore arthropods on soil enzyme activities.

Species-specific fungal enzymatic responses have also been recorded in soil.^[36] Lignocellulolytic enzyme production by saprotrophic basidiomycetes colonizing leaf litter increased during macrofauna and collembola activity. This may be attributed to litter comminution and to fungal physiological responses to grazing. *Hypholoma fasciculare* and *Phanerochaete velutina* (exhibiting fast and extensive growth) increased production of cellulolytic and phospholytic enzymes during macroinvertebrate grazing, whereas the slow-growing species, *Rhizoctonia bicolor* reduced enzyme production. Contrasting enzymatic responses of fungal species suggest the impacts of soil fauna on fungal-mediated nutrient mineralization.

However, a meta-analysis of litter box experiments^[37] showed that soil fauna significantly increased litter removal from the litter layer but did not significantly affect overall C mineralization. The rate of leaf litter decomposition is significantly faster than decomposition of macrofauna feces produced from the same litter. This suggests that larger litter mass loss from soil surface caused by soil fauna may be decoupled from overall litter mineralization. Fauna effect of litter decomposition and mineralization is likely to be affected by climatic condition and litter quality but also by diversity and functional complexity of soil food webs as well as the time for which soil gets exposed to soil fauna. Several studies suggested that long-term fauna effect is more likely to promote C sequestration than mineralization. However, more studies are needed on the role of soil fauna in organic matter mineralization.

CONCLUSION AND FUTURE PROSPECTS

Soil enzymes is a vast research area with enormous potential to be exploited and manipulated for agricultural benefits. The importance of soil enzymes in soil biogeochemical processes, soil health, and agricultural productivity is well

known. Soil enzymes are under the influence of physical, chemical, and biological properties of soil which in turn are influenced by soil management practices, environmental factors, etc. However, there is very little information on this subject due to lack of well-equipped laboratories as well as trained manpower to research in this area to understand determinants of soil enzymes activities. There is an urgent need to develop tools and techniques to assay enzymatic activities with precision and research methodology to conduct experiments in this complex area. With the advancement in molecular techniques, measurement of soil enzyme activity has become possible up to functional microbial communities, gene, transcriptome, and protein levels. The limitations associated with *in situ* enzyme activity need to be addressed to make the measurements more precise and practically feasible. Temporal and spacial studies on soil enzymes activities are needed to know the factors controlling enzymes activities so that optimal conditions for the soil enzymes activities may be understood. Soil enzyme profiling under different cropping systems and management practices can help in developing correlations between soil enzymes activities and productivity and soil health of the ecosystem. Climate change-induced abiotic and biotic stresses affect soil enzymes activities. However, basic and strategic research has to be conducted across agroecological regions to understand dynamics of soil enzymatic activities and interplay of cropping system and agro-techniques under changing climatic conditions to generate enough knowledge that can be used to manipulate activities and interventions in order to improve specific ecosystem functions. This information will also help to design coping mechanisms to maintain soil enzyme activities under climate change conditions and thus sustain crop productivity.

Soil Organic Matter (SOM)

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Soil organic matter (SOM) is essential to maintaining soil quality and providing numerous ecosystem services. Its magnitude in soil depends on climate, soil properties, terrain characteristics, vegetation, and landscape position. Its concentration is more in soils of cooler and humid than warmer and dry climates. There are numerous cost-effective and non-destructive methods of determination of SOM. Its magnitude and dynamics can be modeled and related to several index properties. Managing SOM is essential for advancing food security, mitigating climate change, improving water quality, and enhancing biodiversity.

INTRODUCTION

The origin and importance of soil organic matter (SOM) were appropriately summarized in 1973 by Allison:^[1] “Soil organic matter has over the centuries been considered by many as an elixir of life. Ever since the dawn of history, some eight thousand or more years ago, man has appreciated the fact that dark soils, commonly found in the river valleys and broad level plains, are usually productive soils. He also realized at a very early date that color and productivity are commonly associated with organic matter derived chiefly from decaying plant materials.” The SOM comprises the sum of all organic substances in soil and primarily consists of heterogeneous substances of plant, animal, and microbial origin at various stages of decomposition. Its decomposition products include: 1) soluble organic compounds such as sugars, proteins, and other metabolites; 2) amorphous organic compounds such as humic acids, fats, waxes, oils, lignin, and polyuronides; and 3) organomineral complexes, which involve hybrid compounds of organic molecules attached to clay particles through polyvalent cations such as Al^{3+} , Ca^{2+} , and Mg^{2+} .^[2]

Two principal components of SOM are highly active humus and relatively inert charcoal. Humus is a dark brown or black amorphous material. Being a colloidal substance, it is characterized by a large surface area, high charge density, and high affinity for clay. Charcoal is widely present in soils of the fire-dependent ecosystems (i.e., savanna, steppe, and grasslands). The charcoal, also called black carbon (C), is of pyrogenic origin. It comprises lightly charred organic matter, soot particles rich in graphite, and polycondensed aromatic groups. Highly fertile soils of the Amazon, *terra preta do Indios*, are enriched by the addition of charcoal.

SOM DYNAMICS

In natural ecosystems, SOM is in dynamic equilibrium with its environment. Its amount in the soil is stabilized when the

rate of input equals that of the output. The input of SOM is mainly through residues of plants grown *in situ* and from substances brought in by alluvial, aeolian, and colluvial processes. The output of SOM is through decomposition or oxidation, erosion, and leaching. The rate of decomposition depends on temperature and moisture regimes and is more in warmer and wetter than in cooler and drier climates. Soil erosion, by water and wind, preferentially removes SOM because it is lighter (lower density) than mineral fraction and is concentrated in the vicinity of the soil surface where erosional processes are the most effective. The soluble and colloidal components of SOM are leached into the subsoil and eventually into aquatic ecosystems along with the percolating water. Removal of crop residues for alternative uses, such as traditional or modern biofuels (cellulosic ethanol) and livestock feed, reduces input of biomass and decreases the soil organic C pool. Thus, there is no such thing as a free biofuel from crop residues.

Natural factors affecting the SOM concentration include climate, soil type, vegetation, hydrology, landscape position, and soil biodiversity. Principal climatic parameters are precipitation amount and distribution, temperature and its seasonal and diurnal variation, annual and seasonal water budget, and the duration of the growing season as determined by the degree days and hydrologic balance. Predominant soil properties that affect SOM include texture, clay minerals, pH, ionic composition and concentration, and soil depth. Internal drainage of the soil profile, affecting soil moisture regime, is also important. Landscape affects SOM content through the position, drainage density, slope shape, and slope aspect. Slope aspect determines soil temperature, slope position determines moisture regime, and slope shape determines the sedimentation and depositional processes. Analyses of these factors indicate that once SOM has been severely depleted by natural or anthropogenic factors, it is difficult to restore in tropical agroecosystems, coarse-textured soils, drought-prone environments, and

nutrient-deficit [nitrogen (N), phosphorus (P), and sulfur (S)] conditions. Vegetation, and its residues, influences SOM content through the relative concentration of lignin, cellulose, polyphenols, and other recalcitrant compounds. Root system, its depth distribution, and turnover are also important to SOM stock in the profile, especially in the subsoil horizons. Roots contribute more to refractory SOM (relatively stable soil C pool) than the same amount of above-ground residue-derived C.^[3] Presence of stabilizing elements (especially N, P, and S) is important to converting biomass C into humus.^[4] In drier climates, SOM stock is favorably influenced by the hydraulic lift of deep-rooted shrubs.^[5]

ASSESSMENT OF SOM

There is a long history of determination of SOM concentration in the laboratories.^[6] Concentration of SOM in the laboratory is determined by either the wet combustion^[7] or dry combustion method.^[8,9] There are numerous modern techniques of measuring SOM stock *in situ*,^[10] rapidly and

in a cost-effective manner.^[11,12] There are also molecular-level methods for monitoring SOM concentration in relation to climate change,^[13] including nuclear magnetic resonance techniques and SOM biomarker techniques.^[14–19] Several practical indicators of changes in SOM concentration have been developed.^[20,21] While concentration of SOM in the root zone (measured as % or gram per kilogram) has been the unit of assessment for agricultural and forestry land uses, the assessment at regional, watershed, national, and global scales is done in units of megagram per hectare, teragram, or picogram.

MANAGEMENT OF SOM

The quantity and quality of SOM affect numerous soil processes and ecosystem services of significance at local, regional, and global scales (Fig. 1). The SOM concentration of 2–3% dry soil weight is needed to improve the use of efficiency of inputs and enhancing agronomic production.^[22] It is essential to advance global food security^[23] and create a positive C budget by reducing losses and

Fig. 1 Ecosystem services provided by SOM. Abbreviations: AWC, available water capacity; GHGs, greenhouse gases (e.g., CO₂, CH₄, and N₂O); NPP, net primary productivity.

Table 1 Soil organic matter as a determinant of specific components of soil quality.

Soil physical quality	Soil chemical quality	Soil biological quality
1. Soil structure and tilth	1. Soil reaction (pH)	1. Food for soil organisms
2. Porosity and pore size distribution; biopores	2. Cation exchange capacity	2. Habitat for biota
3. Plant's available water holding capacity	3. Elemental toxicity (Al^{3+} , Fe^{3+} , and Mn^{3+})	3. Microbial biomass carbon
4. Soil erodibility	4. Electrical conductance and salt concentration	4. Products of decomposition
5. Infiltration, percolation, run off, and leaching	5. Plant available nutrients (i.e., N, P, K, Cu, and Zn)	5. Soil respiration rate
6. Crusting, compaction, and hard setting	6. Nutrient/elemental cycling	6. Methanogenesis
7. Soil temperature regime and thermal conductivity	7. Chemical transformations	7. Nitrification/denitrification
8. Gaseous diffusion (diffusion coefficient)	8. Nutrient diffusion	8. Soil C sink capacity
9. Surface area	9. Organomineral complexes	9. Gaseous composition of soil air
10. Soil strength	10. Redox potential	10. Activity and species diversity of soil flora and fauna

increasing inputs of biomass C. Maintenance of SOM above the critical level enhances physical, chemical, and biological processes, which are strong determinants of the overall soil quality (Table 1 and Fig. 2). The processes are enhanced by the adoption of soil-specific practices. Some recommended management practices in agroecosystems include conservation tillage, mulch farming, cover cropping, integrated nutrient management including use of manures, biofertilizers, and biochar; agroforestry; controlled grazing; and improved pasture. Restoration of wetlands, erosion control, and afforestation of degraded and desertified lands are important options of enhancing the

SOM concentration and pool. In 1938, William Albrecht^[24] emphasized that “soil organic matter is one of our most precious resources; its unwise exploitation has been devastating; and it must be given its proper rank in any conservation policy as one of the major factors affecting the level of crop production in the future.” It was in a similar context, in view of the rising energy costs in late 1970s and the suggestion about the use of crop residues for biofuels, when Hans Jenny^[25] stated in 1980 that “I am arguing against indiscriminate conversion of biomass and organic wastes to fuels. The humus capital, which is substantial, deserves being maintained because good soils are a national asset.”

CONCLUSION

Quantity and quality of SOM and its maintenance above the threshold/critical level have been the foundation of past civilizations and are the bases on which the future of mankind depends. Its concentration in the root zone determines numerous ecosystem services including food security, climate change mitigation and adaptation, biodiversity, and water resources. It is the global public good, whose importance to human well-being and ecosystem functions can never be overstated. While strengthening and promoting long-term basic and applied research on processes and practices of its management and assessment at different scales, policy instruments must be in place at national and international levels for its enhancement and sustainable management.

Soil Organic Matter (SOM): Accumulation

Sylvie A. Quideau

Department of Renewable Resources, University of Alberta, Edmonton,
Alberta, Canada

Abstract

Organic matter plays a central role in soil functioning. It acts as a nutrient storehouse, improves soil physical properties such as water retention and porosity, and provides a habitat for soil microbes. Accordingly, organic matter is often used as a proxy for soil quality. Its accumulation reflects the balance between organic matter additions (e.g., littering) and losses (e.g., decomposition). Its extent, type and rate of accumulation vary widely among soils as a function of the five key forming factors, i.e., climate, organisms, relief, parent material, and time. Long-term rates of carbon accumulation in soils vary from 0.2 to 12 gC m⁻² yr⁻¹. Finally, organic matter is an important criterion for classifying soils, in particular to separate organic from mineral soil orders, and secondly to recognize diagnostic surface and subsurface horizons.

INTRODUCTION

Chemical, biological, and physical processes continually transform organic matter (OM) added to soils in the form of plant or animal detritus. Soil OM includes residual components of original organic tissues, their degradation products, and products synthesized by soil fauna and microbes. Two major types of natural organic compounds are distinguished: 1) non-humic substances, belonging to identifiable chemical classes such as carbohydrates; and 2) humic substances, a series of brown to dark brown, high-molecular weight biopolymers distinctive to soil environments.

OM accumulation in soils results from the combination of several pedogenic processes that can be conceptualized and separated into four broad categories, namely: 1) OM additions; 2) transformations; 3) transfers; and 4) losses. OM accumulation is also directly linked to the genesis of soils. Hence it is dependent on defined environmental factors, also known as soil-forming factors, which include climate, organisms, relief, parent material, and time. Finally, OM is recognized as a key attribute of soils, as it is instrumental in the vast majority of soil physical, chemical, and biological properties. With regard to soil classification, the amount of carbon (C) accumulation is used at the higher level to separate mineral from organic soils. At the lower level, the location and type of OM accumulation within a soil profile help identify a series of diagnostic surface and subsurface horizons.

PEDOGENIC PROCESSES

Additions to Soils

Littering refers to the deposition of dead plant and animal detritus on the soil surface (Table 1). As litter decays,

soluble organic products leach into the mineral soil. Alternatively, particulate litter can be incorporated into the soil by faunal *pedoturbation*, which is soil mixing by animals, including termites, earthworms, ants, and rodents. *Root turnover* also may constitute an important addition of C into the mineral soil. In forests, relatively more C is added as surficial litter; in grassland ecosystems, up to two-third of carbon is added through the decay of roots.

OM Transformations

Decomposition refers to the chemical and biochemical reactions occurring during the decay of plant and animal remains as soil microorganisms colonize them (Fig. 1). Decomposition involves the fragmentation of biopolymers into smaller molecules, with carbon dioxide production as the ultimate step in aerobic soils, and methane production occurring in anaerobic environments. Organic litter is composed of distinct chemical components that decompose at different rates. In addition to focused on litter chemistry, including nutrient concentrations and ratios such as the C-to-nitrogen (N) ratio or lignin-to-N ratio, physical attributes of litters affect their decomposition rates.^[1] *Mineralization* releases soluble or gaseous inorganic constituents during decomposition processes.

Humification is a multistage process. Source materials for humus synthesis include residual components from incomplete decomposition of organic litter and the products of microbial anabolic activities. According to traditional concepts, polyphenols derived from lignin degradation, together with those synthesized by microorganisms, are oxidized to quinones, which undergo self-polymerization or combine with amino compounds to form N-containing polymers.^[2] More concepts recognize the importance of

Table 1 Fundamental pedogenic processes associated with OM accumulation.

Term	Definition	Representative horizon (soil order)
Littering	Accumulation of fresh organic detritus on the mineral soil surface to a depth of <30 cm	Oi ^a or L ^b horizon (all soil orders)
Root turnover	Subsurface C addition through root death	
Decomposition	Breakdown of organic molecules into simpler compounds	Oe and Oa ^a , F and H ^b , and A horizons (all soil orders)
Mineralization	Release of inorganic constituents of OM	
Humification	Formation of humic substances from raw organic materials	
Synthesis	Formation of new organic molecules by combination of elements or constituents	
Paludization	Accumulation of thick (>30 cm deep) organic materials on the mineral soil surface	Folistic, histic horizon (Histosols) ^{a,c} Of, Om, Oh horizons (organic soils) ^b
Ripening	Changes in organic soil promoted by entry of air into previously waterlogged material	
Melanization	Darkening of light-colored initial mineral soil by addition of OM	Mollic horizon (Mollisols ^a , Phaeozems ^c , and Kastanozems ^c) Chernozemic horizon (Chernozems) ^b Chernic horizon (Chernozems) ^c Melanic epipedon (Andisols ^a and Andosols ^c) Umbric epipedon (Umbrisols) ^c
Podzolization	Translocation of OM in the soil profile associated with Al and Fe migration	Spodic horizon (Spodosols ^a and Podzols ^c) Podzolic horizon (Podzols) ^b

enzymes of biological origin as important catalysts of the humification pathways.

Accumulation in Organic Soils

Paludization can be considered as a geogenic rather than pedogenic process because it involves deposition of initial parent material. Paludization occurs when conditions impede decomposition, enabling the buildup of a thick mass of organic deposits. Decomposition is hampered by poorly drained conditions, as in Histosols^[3] and organic soils,^[4] and by extreme cold, as in Histels, a suborder of the Gelisols,^[3] and in organic Cryosols.^[4] Under anaerobic conditions, humic substances exhibit a relative accumulation of aromatic C compounds arising from the absence of lignin-degrading fungi. In contrast to paludization, *ripening* refers to the decomposition processes occurring in the organic horizon under oxidizing conditions after exposure to the air.

Surface Accumulation in Mineral Soils

Melanization produces the thick, dark-colored surface horizons characteristic of Mollisols^[3] and Chernozems.^[4,5] The formation of mollic epipedons is promoted by the proliferation of grass roots that constitute a considerable input of plant residues. Another key factor in melanization

is the active faunal community, which contributes to the rapid incorporation of the residues into the mineral soil and favors high initial mineralization rates. In the World Reference Base for Soil Resources,^[5] a chernic horizon is considered a special type of mollic horizon with high biological activity. Subsequent decomposition and humification processes result in the formation of chemically stable, dark-colored humic substances. Multivalent cations, such as calcium, act as bridges between organic colloids and clay particles and stabilize organic substances within the soil matrix. In soils with lower base status, surface accumulation of OM may lead to the formation of an umbric epipedon, as is the case in Umbrepts^[3] and Umbrisols.^[5] In allophanic soils derived from volcanic parent material (Andisols^[3]), OM accumulation is favored by the formation of resistant organic-alumina complexes.

Subsurface Accumulation

Podzolization results in the formation of subsurface horizons of OM accumulation characteristic of Spodosols^[3] and Podzols.^[4,5] Subsurface OM accumulation occurs at the top of the spodic horizon due to the migration of water-soluble organic compounds from the mineral surface.^[7] Soluble organics originate from the decomposition processes of nutrient-poor, acidic organic residues, such as heath and coniferous litter. According to the traditional metal-fulvate theory, organometallic complexes form in the decomposing litter under conditions of low metal saturation, complex more iron (Fe) and aluminum (Al) as they flush down the soil profile with percolating water, and precipitate when the ratio of metal to C reaches a critical level. Other proposed mechanisms for immobilization include flocculation, polymerization, and sorption on mineral surfaces.

ENVIRONMENTAL CONTROLS

The rate of OM accumulation varies greatly among soils, reflecting the influence of environmental factors on pedogenic processes (Table 2):

$$OM = f(\text{climate, organisms, parent material, relief, and time})$$

where *f* stands for “is a function of.”

Climate

Climate influences OM accumulation by controlling the balance between litter production and decomposition rates. On a global basis, soil C content increases with increasing precipitation but decreases with increasing temperature. In situations in which moisture is not a controlling factor, decomposition increases with increasing temperature. Litter production follows the same trend. Therefore, the

Table 2 Long-term accumulation rates of soil C in different ecosystem types.

Ecosystem type	Accumulation interval (yr)	Long-term rate of accumulation (g C m ⁻² yr ⁻¹)

worldwide accumulation of soil OM is related more to factors controlling decomposition than to the productivity of ecosystems. On a local and regional scale, OM content decreases exponentially with rising annual temperature at any given level of precipitation:^[10]

$$OM = Ce^{-kT}$$

where *T* is the mean annual air temperature (°C), and *C* and *k* are constants. On the other hand, OM accumulation does not follow a climatic pattern in poorly drained soils where anaerobic conditions impede decomposition processes.

In addition to its influence on total C content, climate may also affect the chemical composition of soil OM. High rainfall favors high leaching regimes and increases alkyl C while reducing the development of aromaticity in soil OM.^[11] Aromaticity also has been reported to be negatively correlated to the precipitation/temperature ratio. For prairie soils of the Great Plains, polysaccharides decreased with increasing temperature but increased with increasing precipitation.^[12] Similarly, OM composition was reported to change in conjunction with total C stocks along a climosequence of boreal forest soils.^[13] Namely, total soil C stocks (0–1 m) increased with decreasing mean annual temperature, while the degree of OM decomposition decreased along the soil sequence.

Organisms

The amount, placement, chemical composition, and physical attributes of the organic residues of vegetation also affect

OM accumulation. Litter production worldwide declines with increasing latitude from tropical to arctic forests, following the same distribution patterns as net primary productivity. The placement of organic residues affects the distribution of OM accumulation within the soil profile. In grassland soils, where belowground production is abundant, OM is more evenly distributed than it is in forest soils, where most accumulation occurs in the uppermost horizon. The chemical composition and physical attributes of litter both exert a significant influence on the accumulation and turnover of soil OM by determining the palatability of the plant material, which in turn can alter the distribution and activity of soil fauna. Soil animals, such as earthworms, may accelerate decomposition rates by contributing to the rapid mixing of fresh plant residues into the mineral soil.

Climatic factors are often considered to have a greater impact on OM composition than does the original composition of the litter inputs, in other words than the type of vegetation growing on site.^[8] While vegetation and climate are considered as two discrete environmental or independent soil-forming factors, they often covary in natural landscapes, and their independent assessment remains challenging. One potential approach to separate the influence of vegetation from that of climate is to compare a strict biosequence (soils developed under a similar climate but different vegetative covers) and a climo/biosequence (where both vegetation and climate vary). Results from work conducted along two Californian soil sequences suggested that vegetation rather than climate was controlling OM composition.^[2]

Parent Material

Parent material may influence OM accumulation through its effect on soil fertility. Soils formed from base cation-rich volcanic rocks (e.g., basalt) are typically more fertile, and thus experience more OM accumulation than soils with lower inherent mineral-derived nutrients, such as those formed from granitic materials. Parent material is also effective through its determination of soil texture. Soil clay content and OM accumulation are positively correlated. Clay content affects soil moisture and water availability, thereby modifying plant productivity and litter production. Additionally, high clay content may induce OM accumulation by stabilizing humic substances formed during decomposition. Clay and OM form organo-mineral complexes that are resistant to further biodegradation. Lastly, the texture of the parent material may indirectly affect OM accumulation through its influence on structure development. For example, fine textured soils tend to contain more aggregates than sandy soils, and OM may preferentially accumulate within these aggregates.

Relief

Topography interacts with microclimate to influence OM distribution in soils. OM accumulation is often favored at

the bottom of hills where conditions are wetter than at mid or upper slope positions, resulting in lower decomposition losses. In a similar fashion, OM accumulation is usually greater on north-facing slopes compared with south-facing slopes (in the northern hemisphere) because temperature is lower; lower temperatures are conducive to both lower primary productivity and decomposition losses.

Time

Long-term rates of OM accumulation in Holocene-aged soils vary from less than 1 to 12 g Cm⁻²yr⁻¹.^[8] OM, however, does not accumulate indefinitely in soils. Depending on other soil-forming factors, an equilibrium level is reached over time. OM encompasses a series of pools with varying turnover rates. Amounts of the young, labile OM may level off in decades because plant biomass stabilizes, while amounts of the more recalcitrant fractions, composed of humic substances often complexed with clay minerals, may continue to increase for tens of thousands of years.

Human Influence

Human influence is considered as part of the “organisms” environmental factor in the original formulation by Hans Jenny,^[10] alongside with microorganisms, vegetation, and animals. Since then, many authors have proposed that humans be recognized as a sixth soil-forming factor. Human influence on OM accumulation in soils ranges from the simple alteration of a single soil horizon, for instance surficial OM enrichment linked to manure addition, to more drastic changes including the complete reconstruction of entire soils, such as is the case during land reclamation following surface mining. Human-affected soils are starting to get included in several soil classification systems, although a consensus is lacking. For instance, the anthropic and plaggen epipedons are two horizons that exhibit OM accumulation as a result of human activities.^[5]

CONCLUSION

Our appreciation of the importance of OM in soil functioning and our understanding of the factors and processes that control OM accumulation have very much developed alongside the discipline of pedology. As early as the 19th century, Vasily Dokuchaev, commonly regarded as the father of pedology, observed that soils change predictably as a result of their environmental settings. Much of his work focused on understanding the conditions favoring OM accumulation in Chernozems of Russia. At the time, interest in OM mostly arose from its pivotal role in the fertility and overall productivity of soils. Discussions of climate change mitigation and C trading have emphasized the role of soils as an important global C pool. Understanding

how OM accumulation and storage respond to changing environmental conditions is becoming increasingly important to accurately model C at the global scale.

OM accumulation in soils varies horizontally and vertically across the landscape and evolves with time through the combined influence of several pedogenic processes. Soil OM encompasses a series of C pools with differing residence times. Labile C may turnover within days or years, while stable C may persist in soils for thousands of years. In between these two extremes, lies C with intermediate (decadal) turnover rates, which may be of most relevance to the overall soil C response to climatic changes over the next century. Hence, much research is targeted at understanding the factors controlling not only the accumulation of OM in soils but maybe more importantly the stability of the accumulated OM. Lastly, C in subsoil horizons has been investigated less than surficial C. Deep soil C (i.e., below 20 cm) represents more than one-half of the total C stored in soils globally. Understanding the mechanisms responsible for deep C accumulation and stability is emerging as one of the key challenges in soil science.

Soil Organic Matter (SOM): Available Water Capacity

Tom G. Huntington

U.S. Geological Survey (USGS), Augusta, Maine, U.S.A.

Abstract

Available water capacity (AWC) is defined as the amount of water (cm^3 water/ 100 cm^3 soil) retained in the soil between field capacity (FC) and permanent wilting point (PWP). FC and PWP are defined as the volumetric fraction of water in the soil at soil water potentials of 10–33 and 1500 kPa, respectively. One of the paradigms of soil science is that AWC is positively related to soil organic matter (SOM) because SOM raises FC more than PWP. SOM enhances soil water retention because of its hydrophilic nature and its positive influence on soil structure. It improves soil structure by enhancing aggregate formation, thereby increasing porosity in the range of pore sizes that retain plant-available water and enhancing infiltration and water retention throughout the rooting zone. Understanding the sensitivity of AWC to SOM is important for assessments of how environmental changes that influence SOM content could affect AWC and sustainability of agricultural productivity.

INTRODUCTION

Available water capacity (AWC) is defined as the amount of water (cm^3 water/ 100 cm^3 soil) retained in the soil between field capacity (FC) and permanent wilting point (PWP).^[1] FC and PWP are defined as the volumetric fraction of water in the soil at soil water potentials of 10–33 and 1500 kPa, respectively. One of the paradigms of soil science is that AWC is positively related to soil organic matter (SOM) because SOM raises FC more than PWP^[2–4] (Fig. 1). SOM enhances soil water retention because of its hydrophilic nature and its positive influence on soil structure.^[5,6] Increasing SOM increases soil aggregate formation and aggregate stability^[7] (Fig. 2), thereby increasing porosity in the range of pore sizes that retain plant-available water and enhancing infiltration and water retention throughout the rooting zone. When SOM decreases, soil aggregation and aggregate stability decrease and bulk density increases.^[8] These changes in physical properties result in lower infiltration rates and higher susceptibility to erosion.^[9,10] This entry reviews the literature on the sensitivity of AWC to soil organic carbon (SOC) and discusses the environmental implications of changes in SOM and AWC.

SENSITIVITY OF AWC TO SOM

Many studies have determined that AWC decreases as SOM decreases, but considerable variation in this relation has also been reported. A majority of studies have used regression analysis to quantify the sensitivity of AWC to SOM. Other estimates of the relation between SOM and AWC have been obtained from changes in water retention

characteristics over time for a specific soil where different management, fertilization, or erosion histories have resulted in changes in SOM. To facilitate comparison among estimates of the relation between AWC and SOM in this review, sensitivity was defined as the average change in AWC (cm^3 water/ 100 cm^3 soil) predicted for a 5% relative decrease in SOM where the initial SOM concentration was in the range of 2–4% by weight. If texture was included in the published regression, it was held constant at 65% silt, 20% clay, and 15% sand. If bulk density was included in the regression, it was assumed that bulk density decreased with increasing SOM following the regression equation:

$$\text{Bulk density} = 1.723 - 0.212(\text{OC})^{0.5} - 0.0006(\text{WC15})^2$$

where OC = percent soil organic carbon and WC15 = water content at 1500 kPa.^[11] WC15 for a soil with the texture of 65% silt, 20% clay, and 15% sand was assumed to be 11.3 cm^3 water/ 100 cm^3 soil. Where data or regression analysis required transformation of soil organic carbon (SOC) to SOM, it was assumed that $\text{SOM} = 1.724 \times \text{SOC}$.

Reported sensitivities fell in the following ranges (0 to +0.27),^[12–14] (0 to –1),^[15–20] (–1 to –2),^[21–24] and (< -2)^[25–27] (cm^3 water/ 100 cm^3 soil) per 5% relative decrease in SOM concentration. The average value for the sensitivity was $-1.1 (\pm 0.34 \text{ SE}) \text{ cm}^3$ water/ 100 cm^3 soil per 5% relative decrease in SOM concentration. Out of the 15 studies, 3 found a negative or no relation between SOM and AWC. Regression models that indicated no relationship between SOM and AWC typically found that SOM resulted in equivalent increases in water retention at both FC and PWP with the result that AWC did not change.

Fig. 1 Water content at FC and PWP for sandy (A) and silt loam (B) textured soils. *** indicates that the relationship is statistically significant with p -value <0.0001 and ns indicates that the relationship was not statistically significant with p -value >0.05 .
Source: Reproduced from Hudson.^[3]

In addition, two large studies have used the U.S. National Soil Inventory database to study the relationship between SOM and AWC where AWC was based on reported values for FC and PWP.^[28,29] One study^[28] showed a positive relationship between SOM and plant AWC that was dependent on soil texture and reported that FC was more sensitive to SOM than PWP. In another study,^[29] a complex relation was reported such that a 1% increase in SOM causes a 2% to >5% increase in soil AWC depending on the soil texture. Both studies

concluded that coarse-textured soils had a higher sensitivity to SOM than fine-textured soils and that sensitivity decreased as SOM content increased. These two studies^[28,29] are consistent with the findings of most of the other cited studies that have found that increases in SOM result in proportionately larger increases in AWC in medium- to coarse-textured soils compared with finer-textured soils. Most studies found that aggregate stability has been shown to increase with increasing SOM at similar rates across a wide range of clay contents^[7] (Fig. 2). However, in that study^[7] it was also shown that with increasing clay content, soils require a higher SOM content to maintain a given aggregate stability value (Fig. 2). As SOM levels decrease, as occurs following chronic high rates of erosion, the effect of incremental decreases in SOM on AWC becomes progressively smaller. In heavily eroded soils, clay contents become increasingly more important than SOM in influencing hydraulic properties.^[10]

The physical and chemical properties of SOM could influence how SOM affects soil water retention. Differences in SOM quality may arise from differences in inputs, such as natural plant residues, manure, or sludge, or they may result from different soil drainage conditions. These and other factors such as mineralogy, exchangeable cations, and surface chemical properties that can influence the formation and stability of aggregates and mesopores complicate the simple relation between AWC and SOM.^[6]

There are several other possible explanations for the high variability in the reported sensitivity of AWC to SOM. Differences in methods used to measure water retention at both FC and PWP could introduce bias. Both *in situ* and laboratory methods have been used for the determination of water retention at FC and PWP. Laboratory methods can involve everything from intact cores to air-dried, sieved, rewetted, and recompact soil samples.^[1] Any pretreatment that changes soil porosity and soil aggregation will affect estimated water retention. There is no agreed-upon standard water potential for the estimation of FC in the laboratory. Different methods have been used to determine SOC and SOM. Differences in texture, mineralogy, bulk density, coarse fragment volume, and quality of the SOM of the soils used in the regression analyses could mask the effects of SOM. Some reports involve controlled regressions where variables such as texture are held constant. It may not be surprising that in uncontrolled regressions, the effects of SOM are obscured.^[3,6]

Soil water retention data from long-term plots, such as classic crop rotations, fertility experiments, and no-till vs. conventional tillage experiments, may be more appropriate for this type of sensitivity analysis. In these types of experiments, SOM changes measurably over time, but other variables are essentially held constant. However, there have been few reports of this kind. At the Sanborn Field in Missouri, continuous cropping for over a century resulted in large decreases in SOM and soil productivity.^[30] Losses

Fig. 2 Relationship between aggregate stability and soil organic matter content for samples from the Hamble, Lawford, and Denchworth soil series from southern England.
Source: Redrawn from Haynes & Beare.^[7]

of SOM at the Sanborn Field could have increased erosion and loss of topsoil that likely decreased AWC.^[30] However, in another study at the Sanborn Field,^[15] no significant differences in water retention among treatments were observed for soil cores collected between 2.5 and 10 cm depth. A study in Denmark reported that after 90 years of manure additions, AWC was substantially higher on the amended plots than on unfertilized reference plots.^[27] In a 32-year continuous corn experiment, cropping treatments that resulted in lower SOM (removal of corn stover and tillage) reduced SOM by 8% and 25% and decreased AWC by 8% and 13%, respectively.^[31] In a shorter-term study, the addition of manures to grasses, cereals, and sugar beets for seven or more years increased AWC at four sites with different soils in the United Kingdom.^[32]

ENVIRONMENTAL IMPLICATIONS

Environmental changes such as land use conversions, changes in agricultural management practices, climate change, and changes in acidic deposition could affect SOM contents and, consequently, AWC. Land use conversions from grasslands or forests to cultivated agriculture^[33] or intensification of agriculture^[34] are likely to result in net losses of SOM, but improvements in agricultural management practices have the potential to substantially enhance SOM contents and increase AWC.^[35] Historical increases in acidic deposition followed by decreases in decades have been associated with concomitant increases and decreases in SOM in forest soils.^[36,37]

It is generally acknowledged that global mean annual temperature will likely increase in the range of 1.4–5.8°C during the 21st century as atmospheric carbon dioxide

(CO₂) concentrations increase.^[38] However, there is substantial uncertainty in how SOM levels will respond to the associated soil warming and elevated CO₂ concentrations. Some modeling^[39–41] and empirical studies where land use and management were held constant^[42–47] are consistent with declines in SOM following increases in temperature, but other environmental factors cannot be ruled out. Other studies suggest only no or small declines in SOM with increasing temperature or increases in SOM if precipitation increases along with increasing temperature.^[48–51] In one study^[52] it was concluded that temperature affects SOM polymerization and adsorption and desorption to mineral surfaces as well as the production and conformation of microbial enzymes. They argued that the net effect of these processes on the availability and degradability of SOM will determine how SOM will be affected by increasing soil temperatures. In another study,^[53] it was reported that warming accelerates decomposition of decades-old carbon in forest soils. In yet another study,^[54] elevated CO₂ was shown to have a priming effect on the decomposition of older SOM and to accelerate the decomposition of new detrital inputs. Complex relations have been reported between SOM and temperature and CO₂ that suggest both increases and decreases in SOM,^[52,55,56] with the result that there is no consensus on the overall effect of these environmental changes on SOM in soils.

In areas where climate change results in a hotter and drier environment with more variability and extreme events of drought and heavy rainfall, as has been predicted for some regions,^[57,58] soils will be subjected to more influence from a number of processes that are conducive to structural degradation.^[59] Soil aggregate stability and soil structural integrity are likely to be adversely affected by losses in SOM that would accompany drying conditions.

Fig. 3 A conceptual model of the major effects of decreasing SOM on soil physical properties that interact through the loops shown to decrease available water capacity in cultivated, eroding agricultural fields.

Structural degradation is associated with a loss in AWC and crop water use efficiency and increasing susceptibility to erosion. Decreases in SOM content would have adverse effects on soil chemical and physical properties because of the importance of SOM to soil structure and hydrologic properties. SOM is important for the maintenance of good soil structure through its positive influence on soil aggregate formation and stability^[7] (Fig. 2). Aggregation increases soil porosity and provides for improved water retention within the range of soil water potential where water is available to plants. It has been recognized that decreases in SOC could reduce AWC and soil fertility with resulting adverse consequences on soil health and productivity.^[60,61]

Reductions in SOM in the surface soil result in increased bulk density, decreased porosity, and increases in matric potential that, in turn, result in decreased AWC (Fig. 3). Decreases in SOM also result in decreases in soil aggregation, aggregate stability,^[62,7] and macropore continuity, thus causing increases in surface crusting and decreases in hydraulic conductivity (Fig. 3). These changes in physical properties lead to reduced rates of water infiltration and increases in runoff and erosion.^[10] A climate warming-induced intensification of the hydrologic cycle could increase runoff and erosion in some regions.^[63] Decreased infiltration and increased runoff result in less precipitation retained throughout the soil rooting zone so that less precipitation becomes available for plant growth. SOM exerts a strong influence on AWC through these interacting feedback loops that affect many soil physical properties (Fig. 3).

CONCLUSION

Despite considerable uncertainty in the relation between AWC and SOM, most studies are consistent with the classical conceptual understanding that these soil properties are positively related. SOM promotes soil aggregate formation and the development of soil porosity that enhances infiltration and retention of water in a range that is available to plants. Environmental changes that result in increases in SOM will increase AWC. On the other hand, environmental changes that result in decrease in SOM will decrease AWC with resulting adverse consequences for the sustainability of agricultural productivity in some regions. There is a need to improve the quantitative understanding of the sensitivity of AWC to SOM to reduce the level of uncertainty and to provide resource managers with better decision support systems.

Soil Organic Matter (SOM): Characterization

Christian Feller

Institute of Research for Development, Montpellier, France

Abstract

Originally, the meaning of “humus” was “soil” in Latin. By the middle of the 18th century, this original sense survived in the European scientific literature along with the concepts of soil layer (the humus-horizon concept) and soil constituent (the humus-constituent concept). The humus-horizon concept was mainly developed by foresters from the mid-19th century, and it contributed to the emergence of pedology. Humus as a constituent was studied by chemical techniques till the end of 19th century. Soon after the emergence of microbiology, the role of microbial metabolites in humic substance formation was questioned, but it was only in the 1960s that the concept of microbial biomass emerged (Jenkinson, 1966) and developed a lot. At the same time, the era of a physical approach to soil organic matter opened.

INTRODUCTION

Widely different meanings are attached to the term humus, which have persisted through the present time.

The entry “Humus” in the “Encyclopaedia Universalis Duchaufour” (1970) reads as follows:

stricto sensu, “humus” refers to the fraction of SOM which has undergone a more or less rapid transformation of biological as well as physicochemical origin ... lato sensu ... (the humus) ... designates the ensemble of organic horizons. (The original French or German quotations are not given here, but only their English translation.)

Thus, the same word is used to describe two very different concepts: humus as a constituent and humus as a soil horizon. This entry deals with the development of these two concepts over the past three centuries.

All references cited in the text for authors and years can be found in the historical review papers.

THE DIFFERENT MEANINGS OF THE WORD HUMUS

For the Roman writers, humus meant soil or earth.^[1,2] Cicero (106–43 B.C.) replaced the word “humus” by “terra,” sourced from French “terre” (earth), “terreau,” or “terre végétale” (mold), which survived until the 18th century.

The word “humus” re-entered the European scientific vocabulary in the 18th century. It was used by Wallerius in his “Mineralogy” (1753). In Diderot and d'Alembert's Encyclopaedia (1765), humus signifies vegetable mold. But in 1781, in the Abbé Rozier's *Cours complet d'agriculture* (Full Courses in Agriculture), a famous French dictionary of agriculture, humus was largely mentioned in numerous

entries. However, its meaning remained still not precise, denoting “vegetable mold,” “mold,” or “constituent.”

In the first edition (1809, in German) of his *Grundsätze der rationellen Landwirtschaft* (Rational Principles of Agriculture, or in French *Principes raisonnés d'agriculture*, 1811), the German agronomist Thaer, the father of the “humus theory,” gives a very precise definition of humus restricted to the notion of constituent, the properties of which (composition, reactivity, and extractability) were greatly detailed by the author through an approach that was very complete for that time and is still acceptable today.

Through the 18th century, investigations were carried out both on the “humus constituent” (in connection with the rise of chemistry and then microbiology) and, later on, on the “humus horizon” (in connection with forestry research and the emergence of pedology).

HISTORICAL ACCOUNT OF THE HUMUS-HORIZON CONCEPT

Hundeshagen (1830) was the first to introduce a morphological classification of forest humus, quoting two types of humus, followed by Emeis in 1875 (three humus types including the present-day mull).^[1,2]

But it was Müller, in his noteworthy works *The Natural Forms of Humus* (1879, 1884, and 1889), who laid the present-day scientific bases of the study on the different forms of humus, and even of a general survey of soil genetic processes in cold and temperate climates. He defined “Mull,” “Mor,” and “Mullartiger Torf” (equivalent to Moder). His book (1889) can be regarded as a treatise, still valid, on the changes of brown soils to Podzols.^[3] Müller has to be considered as one of the main forerunners of pedology. The other names that should be mentioned here include Ramann (1893), who described the “coarse

humus" (Rohhumus), Henry (1908) for biological processes of litter decomposition, Kubiena (1953) for the morphological approach and classifications, and many others such as Wilde (1954 and 1971), Duchaufour (1956), and Delecour (1980).

Delecour's classification inspired the new French system of soil classification [référentiel pédologique Français (RPF, 1990)], and in soil taxonomy (Soil Survey Staff, 1975), the different types of humus are also taken into consideration while characterizing the "diagnostic horizons," the "epipedons," and, especially, the "organic materials."

HISTORICAL ACCOUNT OF THE "HUMUS-CONSTITUENT" CONCEPT

Three main approaches—namely chemical, microbiological, and physical—corresponding to different concepts on soil organic matter (SOM) pool can be distinguished:

The Chemical Approach

Few natural substances attracted chemists' attention as did humus.^[1,2,4–7] Waksman^[5] evokes the "glossary" and the "chaos" of humic substances.

Achard (1786) was probably the first to initiate a long series of studies on the fractionation of SOM by the extraction of peat with alkali and obtention of a dark amorphous precipitate upon acidification. He was followed by Vauquelin (1797) who discovered a blackish substance in the exudates of the wounded bark of elm (Latin "ulm"), named "ulmin" later. In 1822, Döbereiner created the term "humic," and, as early as 1830, the vocabulary became appreciably enriched.

The hymatomelanic acids (alcohol-soluble SOM) were described by Hoppe-Seyler in 1889. Many others can also be cited here. But the qualifier "fulvic," still in continued use along with the terms "humic" and "humin," did not enter the fractionation vocabulary before 1919 with Oden.

Numerous procedures for extracting humic substances were tested in relation to different objectives.^[6–9] It would appear that there was a need at the international level for standardized extraction procedures and agreement about definitions of humic substances (International Humic Substance Society, 1983).

The Microbiological Approach

In 1877, Schloesing and Müntz, using chloroform as an antiseptic agent, discovered the major role of bacteria in the nitrification process.^[2] The origin of humus was thus questioned: plant and/or microbial? Contribution of microorganism metabolites to humic substance formation is ancient: Braconnot (1834) and Lucas (1841) for fungi^[5] and Kostychev (1886) for bacteria.^[6] Maillard (1913) proposed that microorganisms

only played a role during the stage of decomposition of plant residues and the release of monomers but not during the formation of humic substances that are completely chemical. In contrast and at the same time, working independently, both Dumont (1913) and Trusov (1916) distinguished two sources for humus: 1) the "inherited humus" formed by the plant debris or components that resisted humification and 2) the "microbial humus," which they considered as very active especially in nitrogen dynamics (Dumont's nomenclature).^[6]

Jenkinson (1966) was the first to quantify "microbial biomass" by a simple method using soil fumigation with chloroform. This completely new quantitative concept was ultimately based on the forgotten past works such as those of Müntz (1875) and Schloesing and Müntz (1877) and also based on the works of Wollny (1902), Deherain and Demoussy (1896), and Stoklasa and Ernest (1905).

The Physical Approach

Since 1970, the relevance of pure chemical approaches to SOM for the understanding of the role of SOM in soil properties and functioning has been questioned (Anderson et al., 1983; Tiessen and Stewart, 1983); instead, the use of a different SOM characterization based on particle size and/or density fractionations has been developed.^[2,10] But is the latter concept so recent?^[10]

The first elaborate particle size fractionation of SOM was carried out under suitable experimental conditions by Schloesing in 1874, which attracted much criticism; this work could practically be published. Concerning the process of flocculation, Schloesing questioned the distribution of organic matter (OM) between sand and clay in natural samples and thus set out an SOM fractionation in five particle size fractions as follows: "coarse and fine sands," "scales," and two "clay deposits." One of the Schloesing's conclusions was that:

clay contains 69% organic matter; it is enough to be actually modified in the way it acts as a cement.

Henin and Turc in 1950 proposed a density SOM fractionation using benzene–chloroform mixtures of known densities to separate a "light" fraction ($d < 1.75$), named "free OM," essentially constituted of plant debris from a "heavy" fraction ($d > 1.75$), more humified and named "OM bound to inorganic constituents," and "constituted in particular by the clay–humus complex."

This densitometric approach has essentially been developed between 1950 and 1970 by French scientists (Monnier et al., 1962; Duchaufour and Jacquin, 1966; Dabin, 1971) as a preliminary step in humus fractionation. This approach was further advanced by Greenland and Ford (1964) and Ford et al. (1969) who improved the separation of "free OM" by combining sonication (for disrupting aggregates) with densitometry ($d = 2.0$).

Edwards and Bremner, in 1964 and 1967, have shown the effectiveness of sonication in dispersing the soil in water, with no need for a preliminary oxidation of OM or the addition of a dispersing agent. Particle size fractions can thus be separated together with the associated OM. This work is of cardinal importance as it provides a practical method for locating OM among particle size fractions, with no interfering chemical reaction likely to denature the organic or inorganic constituents. This opened the era of particle size fractionation for SOM studies and bio-organomineral interactions.

Rapidly different forms of energy were combined for the process of dispersion, such as chemical dispersants, sonication, shaking with beads (Bruckert et al., 1978; Balesdent et al., 1991), and using Na resins (Feller et al., 1991; Gavi-nelli et al., 1995).

The combinations of both densitometry and granulometry techniques are often used for the characterization of SOM in particle size fraction of aggregate classes.

CONCLUSION

With the two concepts remaining still, the meaning of the word “humus” is unprecise. One can advise the use of it more in the sense of a horizon concept and keep “SOM” for humus as a constituent. Nevertheless, the qualifier “humic” and its derivatives are always used in the sense of a “constituent,” e.g., “humic substances.” But what is important now is to look at how humus was involved in the history of agronomy and ecology (see *Soil Organic Matter (SOM): Historical Concepts*, p. 2139).

Abstract

Molecular studies of soil organic matter are extremely useful to analyze its composition, origin, and dynamics. In this entry, we discuss advances in the field of organic matter studies, which have been achieved by modern spectroscopy and spectrometry including the analysis of stable isotopes. Results suggest that chemical recalcitrance may not be of major importance for carbon stabilization in soil.

INTRODUCTION

Maintaining or increasing organic matter levels in soils is a vital task for good soil management. Soil organic matter (SOM) is a continuum of substances in all stages of decay. Some of these substances may be subjected to stabilization and remain in soil for up to several thousand years. To act on SOM levels and on the amount of easily decomposable material, it is important to know which organic constituents are likely to be stabilized in soil and which are not. Out of the wealth of organic materials entering soils, only a small amount of molecules are ultimately subject to stabilization. However, the identification of these molecules by chemical analyses has not been achieved. In 2001, a consortium of experts on the chemistry of organic matter in the environment stated that more than half of the organic matter in soils remains uncharacterized on a molecular basis despite research efforts lasting for several decades.^[1]

Before the introduction of analytical methods that can be used to characterize solid samples, only the soluble part of the organic matter could be subjected to detailed chemical analysis. Solubilization in alkaline media might introduce artifacts and does not give access to all the organic matters present in soil. Therefore, studies based on the chemical solubility of soil organic constituents might give misleading results. Furthermore, such results are not related to the biological functioning of soils or to the dynamics of their organic constituents. With the application of spectroscopic techniques to soil science, complete information on the bulk chemical composition of SOM could be obtained. However, spectroscopic methods are insensitive, while providing limited information on functional groups

present in SOM. More detailed molecular-level information may be obtained by wet chemical analysis and pyrolysis coupled to gas chromatography and mass spectrometry. Substantial progress in the understanding of the relationship between SOM composition and its dynamics was made when these molecular-level techniques were coupled to isotope quantification [of carbon-13 (^{13}C) and carbon-14 (^{14}C)].

In this entry, we present a state-of-the-art discussion on the milestones and the results obtained in SOM research by using molecular studies. Molecular-level information greatly improved our understanding of SOM composition in relation to its origin, function, and dynamics (Fig. 1). We present information obtained from spectroscopic approaches, analytical pyrolysis, wet chemical analysis, and isotopic methods, concerning the bulk chemical composition of SOM and its dynamics in view of SOM function as long-term C stock.

BULK CHEMICAL COMPOSITION OF SOM

According to molecular analysis of humic substances, extracted from soil with sodium hydroxide, SOM was thought to contain a complex mixture of highly aromatic macromolecules, which are resistant to decomposition owing to their chemical nature. With the introduction of solid-state ^{13}C nuclear magnetic resonance spectroscopy, the paradigm of increasing aromaticity during the formation of SOM was challenged. Studies on organic forest floor horizons indicated that the contribution of aromatic C remained constant throughout the soil profile.^[2] The high contribution of aromatic compounds to organic matter of

Fig. 1 A combination of methods (chemical characterization and isotopic studies) is necessary to understand the complex properties and functions of SOM, which act at the molecular level and may have major environment implications.

some soils was related to the presence of substantial amounts of charcoal produced by vegetation fires.^[3] Nitrogen (N), which had long been suspected to be of stable heterocyclic nature in soils, was shown to be mainly amide N, derived most probably from proteins.^[4] With these results, the nature of organic matter as a mixture of macromolecular humic substances was questioned. It was shown that instead of macromolecules, substances with lower molecular weight are more likely to survive in soil. For example, studies with analytical pyrolysis showed that polysaccharides and proteins may have a much longer residence time in soils than molecules derived from lignin or other macromolecular substances.^[5] From these findings, a new theory emerged after which the microbial loop could possibly be crucial for organic matter stabilization in soil. Under these conditions, the origin of stabilized C may be seen in a new light. It is probably not the precursor substance as itself, which is preserved in soil, but its constituting C, after integration into new (microbial-derived) molecules.

In soils on which no anthropogenic materials, such as compost or sewage sludge, are added, the ultimate source of SOM is plant material. Plant residues consist of above and belowground material. For the management of plant litter input, the above or belowground origins of soil C are of vital importance. However, this question has rarely been addressed, as the quantification of litter input from roots is extremely difficult. The few studies that exist provide evidence that root-derived C may be present in soil in larger amounts than shoot-derived C.^[3,6–8] Molecular studies taking advantage of cutin and suberin as aliphatic

biomarkers of root- and shoot-derived C are of great use to trace the origin of soil organic C.

DYNAMICS OF SOM

The molecular dynamics of SOM is essentially related to the decomposition and incorporation of its precursors constituting plant material. As such, the dynamics in soil of the main plant litter compounds, lignin, carbohydrates, and lipids has been estimated. For such investigations, coupling of molecular and isotopic analysis is necessary. The most suitable technique is the analysis of the stable C isotope ratio of single molecules after separation by gas chromatography. With this technique, the incorporation of the precursor molecules into SOM may be studied on sites, which were subjected to a C3–C4 vegetation change. To carry out a kinetic study, suitable field trials are necessary. Using this technique, Dignac et al.^[9] were able to show that lignin, which is degraded slowly in the first stages of litter decomposition, turns over in soil at a much higher rate than total C. Along with similar results obtained by Wiesenberger et al.^[8] for the lipid fraction, these findings question the generally admitted idea that aromatic and aliphatic substances are the main precursors of SOM. By contrast, carbohydrates, which were considered among the most labile SOM compounds, were found to turn over at a similar rate as total soil C in some physical fractions of soils.^[10] These results are likely to change our understanding of SOM formation. To this end, it was suggested that microbial

C may be an important factor for the stabilization of SOM. Investigations on the dynamics of microbial C using ^{14}C activity measurements on a molecular level showed that it may be very old.^[7] However, the age of microbial C is related to the age of the substance the microorganisms feed on. The very old age of some microorganisms was related to their capability to degrade ^{14}C -free lignite or coal present in some soils. All these molecular studies of SOM dynamics tend to suggest that inherent chemical recalcitrance of SOM precursors is not responsible for their long-term stabilization in soils.

CONCLUSION

SOM has attracted the attention of soil scientists for its importance for soil quality and C sequestration. Studies of the composition of SOM have evolved during the last decades from solubilization techniques, poorly related to the functions and dynamics of organic constituents, to spectroscopic and molecular-level techniques. Molecular-level studies led to great progress in the understanding of the chemical composition of SOM. Coupling molecular with isotopic techniques induced essential progress in understanding the dynamics of plant litter compounds. Molecular dynamic studies suggested that chemical recalcitrance of plant-derived molecules might not be the determinant factor for their preservation in soils.

Soil Organic Matter (SOM): Global Carbon Cycle

Keith Paustian

Natural Resources Ecology Lab, Colorado State University, Fort Collins, Colorado, U.S.A.

Abstract

Soil organic matter (SOM) comprises an integral component of the global carbon (C) cycle, both as the largest overall repository of C within the terrestrial system and as a major source and sink for C exchanges between the atmosphere, terrestrial vegetation, and aquatic environments. Consequently, SOM plays a significant role in regulating the composition of the atmosphere, particularly with respect to carbon dioxide (CO₂). Thus, there is both concern that the effects of climate and land use change on soils will exacerbate the problem of increasing CO₂ in the atmosphere and hope that through better management, soils can play a part in mitigating increasing CO₂ levels.

CARBON COMPONENTS OF SOIL

Carbon (C) is present in both inorganic and organic forms in soil. With the exception of some soils formed on carbonate-rich parent material or arid soils containing high levels of primary or secondary carbonates, organic forms of C predominate in soil. These organic compounds range from fresh plant residues—which are the primary source of soil organic matter (SOM)—to highly recalcitrant, amorphous humic substances. Plant residues are broken down by the soil biota, chiefly microorganisms, to derive energy (i.e., respiration) and C and nutrient elements needed to grow and reproduce. The soil biota comprises a complex food web in which microbial-, plant-, and animal-derived materials are continually consumed, decomposed, and reformed as soil biomass and other secondary compounds. Plant compounds that are not fully metabolized by the biota, e.g., lignin derivatives, microbial metabolites, and other organic substances, can also recombine through chemical and physical reactions. Thus, the decomposition process can be viewed as a “cascade” of biophysicochemical reactions and products,^[1] resulting in the loss of C via respiration, together with the formation of a wide array of secondary SOM compounds including complex recalcitrant substances that can persist in soil for several hundreds to thousands of years.

C STOCKS IN SOIL

C comprises a relatively minor component of most soils, in terms of mass. Most soils contain from 1% to 10% C by mass in surface horizons, with the majority having C contents in the range of 1–3%. The most notable exceptions are soils formed under waterlogged conditions, which restrict the flow of oxygen to soil organisms, greatly reducing the

rates of SOM decay. Such organic soils or “Histosols” may contain 10–30% or more of their total dry mass as C. Despite this generally low concentration, on an area basis, the C contained in soils usually exceeds that contained in the living and dead vegetation (Table 1). Estimates of the global C stock in soils vary, although estimates are on the order of 1,400–1,600 Pg (petagram = 10¹⁵ g = billion metric tons) organic C^[3,4] and 700–900 Pg inorganic C.^[5] Concentrations of organic C are highest in wetlands and in cold, wet environments (e.g., boreal forest) where decomposition rates are suppressed and are lowest in desert and tundra soils where plant productivity, and hence C additions to soil, is low. Stocks of inorganic C are greatest in desert and semiarid to subhumid grasslands and savannas, where carbonate leaching is restricted and the formation of secondary carbonate minerals is favored.

C FLUXES

The carbon dioxide (CO₂) exchanges between the atmosphere, vegetation, and soils are among the largest annual fluxes in the global C cycle (Fig. 1), which are clearly detectable in the regular, seasonal variations in atmospheric CO₂ concentrations. Global estimates of net primary production expressed as C assimilated by live plants (minus respiration) are on the order of 60 Pg C/yr.^[2] Much of the annually produced biomass is added to the soil and soil surface each year as senesced leaves, roots, and woody debris. Emissions of CO₂ from soils through decomposition processes (via heterotrophic respiration) are thought to be on the order of 50 Pg/yr with additional losses of about 10 Pg/yr from disturbances such as fire.^[2] If terrestrial biome C stocks were at equilibrium, then additions of C through net primary production would

Table 1 Global C stocks in soil and vegetation by major biome types.

Biome	Area (10 ⁶ km ²)	Average C density (Mg ha ⁻¹)	Soil C stock (Pg)	Vegetation C stock (Pg)
Tropical forests	17.6	123	216	212
Temperate forests	10.4	96	100	59
Boreal forests	13.7	344	471	88
Tropical savannas	22.5	117	264	66
Temperate grasslands	12.5	236	295	9
Deserts and semideserts	45.5	42	191	8
Tundra	9.5	13	121	6
Wetlands	3.5	642	225	15

be fully balanced by losses through decomposition and other emission sources such as fire. However, overall estimates of the global C cycle suggest that a net accumulation of C presently occurs in terrestrial vegetation and soils, at a rate of about 2 Pg C/yr (Table 2). During the 1980s, tropical regions are believed to have been a net source of C emissions, largely through deforestation. Similar global estimates for the 1990s have not been reported, but if the tropics remain a net source of C from

Fig. 1 Simplified depiction of the global C cycle. Total stocks of C in the atmosphere (as CO₂), oceans, vegetation, and soils + detritus are shown in bold and approximate annual gross fluxes between the major biosphere pools are shown in italics. Dashed arrows denote direction and magnitude of the net flux of CO₂ from industrial sources (mainly fossil fuel combustion) and net sinks to terrestrial and marine environments, estimated as averages for 1990–1999. All stock values are in units of Pg (i.e., billion metric tons) and fluxes are Pg/yr.

Source: Adapted from IPCC^[2] ©2000 Cambridge University Press, Schlesinger^[6] ©1995, and IPCC^[7] ©2001 Cambridge University Press.

deforestation, then the size of the terrestrial sink outside the tropics would be correspondingly greater. In the global budget, the terrestrial sink term is calculated as a difference between the estimates of fossil C emissions, ocean uptake, and observed increases in atmospheric CO₂. The existence and relative size of the inferred terrestrial sink are broadly consistent with estimates of a northern hemisphere terrestrial sink, based on atmospheric transport models^[8]—although considerable uncertainty as to the magnitude and geographic distribution of the sink remains.^[9]

SOIL C FLUXES AND GLOBAL CHANGE

While the net terrestrial accumulation of C is small relative to the annual fluxes of C between the atmosphere and land, it is extremely significant in relation to the net change in CO₂ in the atmosphere. In other words, if the terrestrial C sink was to disappear, and everything else remained equal, the rate of growth of CO₂ in the atmosphere would increase by more than 50%, from about 3.2 to over 5 Pg/yr (Table 2).

The origin of and controls on this terrestrial C sink are not well understood. Model estimates^[10] attribute much of the sink to increased plant growth rates due to higher CO₂ concentrations, although other factors such as nitrogen deposition and changing land use contribute as well. The contribution of soils to the overall C sink is uncertain although it is hypothesized that most of the C accumulates as biomass and surface litter pools. In part, this is to be expected due to the lag time between C accumulation in biomass and fresh residue pools, and its subsequent appearance in more stabilized SOM pools, as well as the fact that much of the C added to soils is relatively rapidly decomposed and evolved as CO₂. Global accumulation of refractory humic compounds in mature native ecosystems has been estimated at 0.4 Pg/yr and it has been suggested that these increases roughly balance leaching losses and long-term average organic C transfers to oceans.^[11] Soil C increases attributed to global afforestation and forest

Table 2 Major net sources and sinks of C in the global budget for the 1980s and 1990s.

	1980–1989	1990–1999
Atmospheric increase in CO ₂ –C	3.3 ± 0.1	3.2 ± 0.1
Emission of C from fossil fuel and cement	5.4 ± 0.3	6.3 ± 0.3
Ocean–atmosphere flux	–1.9 ± 0.6	–1.7 ± 0.3
Land–atmosphere flux	–0.2 ± 0.7	–1.4 ± 0.3
Net from land use change	1.7 (0.6–2.5)	NA
Net from other terrestrial sinks	–1.9 (–3.8–0.3)	NA

regrowth, since the 1950s are estimated to be on the order of 0.1 Pg/yr.^[12] Global estimates are lacking for other ecosystems, but inventories for the United States^[13] suggest that soils in cropland and grazing land represent a small sink, on the order of 10–30 Tg/yr (teragram = 10^{12} g = million metric tons), which can be compared to estimates for C increases in U.S. forest biomass of about 210 Tg/yr.^[14]

The potential feedbacks of climate change on soil C stocks are being debated. Since both plant production (hence, C inputs) and decomposition (hence, C losses) are affected by changes in temperature, precipitation, and CO₂ concentrations, the interactions and feedbacks controlling the terrestrial C balance are complex and difficult to predict. Earlier estimates, assuming a stimulation of decomposition due to projected increases in temperature, suggested that soils could become a significant net source of CO₂, on the order of 40–60 Pg over a 50–100-year period, under a climate regime predicted for double CO₂ concentrations.^[6,15] Other studies suggest that including positive effects of CO₂ on plant productivity, management, and together with adaptations in land might largely offset climate-driven increases in decomposition potential.^[16,17] Debates^[18–20] have highlighted the complexity and continuing uncertainty of how temperature increase, and other changes in climate and CO₂, may impact soils and the global C cycle.

The other significant driver of soil C changes is land use and management. It is well established that the conversion of native ecosystems (e.g., forests, grasslands, and wetlands), primarily to agricultural uses, has led to significant losses of C from terrestrial ecosystems, on the order of 120–170 Pg C or more over the past 150–300 years from vegetation and soils combined.^[21] From soils alone, estimates of historical losses over the same period are 50–100 PgC.^[22,23] However, this legacy of land use offers an opportunity to reverse the historical trend and through better management of soils, exploit their potential to become a significant sink for CO₂. A variety of management options are available to increase soil C storage in agricultural^[24] and other managed ecosystems.^[2] Estimates suggest that potential C sequestration through improvements in land use and management, globally, is on the order of 1 Pg/yr.^[2] Thus the role of SOM in the global C cycle, and how it will respond to changes in climate and land use, will be determined by both the natural forces regulating the earth's biosphere as well as the social, economic, and political actions of human kind.

Soil Organic Matter (SOM): Global Distribution

Wilfred M. Post

Oak Ridge National Laboratory, Oak Ridge, Tennessee, U.S.A.

Abstract

Over long periods of time, organic matter in soils is the result of climatic, biological, and geological factors. These factors are not independent. Over shorter periods of time, soil carbon varies with vegetation disturbances and changes in land use patterns that affect rates of organic matter input and its decomposition. Evidence from long-term experiments suggests that carbon losses due to oxidation and erosion can be reversed with soil management practices that minimize soil disturbance and optimize plant yield through fertilization.

INTRODUCTION

Globally, the amount of organic matter in soils, commonly represented by the mass of carbon (C), is estimated to be 1200–1500 Pg C (1 Pg C = 10^{15} g C) in the top 1 m of soil.^[1,2] This is 2 to 3 times larger than the amount of organic matter in living organisms in all terrestrial ecosystems.^[1] The exact ratio between living and dead organic matter in terrestrial ecosystems varies, depending on the ecosystem. The amount of C stored in soil is determined by the balance of two biotic processes—the productivity of terrestrial vegetation and the decomposition of organic matter. Each of these processes has strong physical and biological controlling factors. These include climate; soil chemical, physical, and biological properties; and vegetation composition. Interactions among these controlling factors are of particular importance. These biological and physical factors are the same as the ones that influence the aboveground structure and composition of terrestrial ecosystems, so there are strong correspondences between soil organic matter content and ecosystem type.

ORGANIC MATTER INPUTS

Quantity

The amount of C stored in soils is to a great extent determined by the rate of organic matter input through litterfall, root exudates, and root turnover. The main factors that influence vegetation production are suitable temperatures for photosynthesis, available soil moisture for evapotranspiration (ET), and rates of carbon dioxide (CO₂) and water exchange. Dry and/or cold climates support low vegetation production rates and soils under such climates have low organic matter contents.

Where climates are warm and moist, vegetation production is high and soil organic matter contents are correspondingly high. Fig. 1 shows the striking correspondence between soil organic matter content and general climate measurements, which results from the relationship between vegetation production and suitable moisture and temperature conditions.

Vegetation production depends not only on climate but also on nutrient supply from decomposition and geochemical weathering. Walker and Adams^[6] hypothesized that the level of available phosphorus during the course of soil development is the primary determinant of terrestrial net primary production. Numerous workers have examined this hypothesis. Tiessen, Stewart, and Cole^[7] and Roberts, Stewart, and Bettany^[8] found that available phosphorus explained about one-fourth of the variance in soil organic matter in many different soil orders. The relationship between phosphorus and C is strongest during the aggrading stage of vegetation–soil system development.^[9] Initially, the production of acidic products by pioneer vegetation promotes the release of phosphorus by weathering of parent material. Organic matter builds up in the soil, increasing the storage of phosphorus in decomposing organic compounds. Nitrogen (N)-fixing bacteria populations, which depend on a supply of organic C and available phosphorus, can grow to meet ecosystem demands for N. Plant growth is enhanced by this increasing N and phosphorus cycling, resulting in increased rates of weathering. This process continues until the vegetation is constrained by other factors affecting phosphorus availability: Leaching losses become larger than the weathering inputs;^[10] an increasing fraction of the phosphorus becomes unavailable by adsorption or precipitation with secondary minerals;^[11] or N availability (denitrification or leaching is affected) reaching or exceeding N inputs and fixation.^[12] In mature soils, net primary production is more likely to be limited by N. Availability of other

Fig. 1 Contours of soil C density (kg m^{-2}) plotted on Holdridge diagram for world life zone classification. Values of biotemperature and precipitation uniquely determine a life zone and associated vegetation. Contour lines for mean soil C content in the surface meter of soil are determined from data derived from over 3000 soil profiles.

Source: From Holdridge,^[3] Zinke, Stangenberger, et al.,^[4] and Post, Pastor, et al.^[5]

nutrients that are largely derived from parent materials, such as most base cations, may also influence soil organic matter accumulation during early soil development.^[13] Soils derived from base cation-rich volcanic parent materials (Andisols) have much higher C contents on average than soils from other parent materials.^[4]

Species Composition

Biotic factors, in particular plant species composition, also affect soil organic matter dynamics. Production and decomposition rates are to some degree controlled by species composition. Each terrestrial plant species produces different amounts and chemical compositions of leaves, roots, branches, and wood of varying decomposability. This range of decomposability may be summarized by the lignin and N content of the organic material.^[14,15] Litter decay rate is inversely related to C/N and lignin/N ratios and positively related to N content. Species with tissues that have low nutrient or high lignin content produce litter that is slow to decay. N is made available to plants during

the decomposition process. N is a limiting element for productivity in most terrestrial ecosystems so the rate at which it is released during decomposition is an important factor in ecosystem production. Thus, the interactions between processes regulating plant populations and their productivity and microbial processes regulating N availability result in some of the observed variation in soil C and N storage.^[16–19]

Placement

The deeper the fresh detritus is placed in the soil, the slower it decomposes. This is a result of declining decomposer activity and increased protection from oxidation with depth in the soil. Prairies have a somewhat lower productivity than forests and produce no slowly decomposing woody material. Nevertheless, prairies have a very high soil organic matter content because prairie grasses allocate twice as much production to belowground roots and tillers than to aboveground leaves.^[20] The result is high soil organic matter contents with a uniform distribution in the

Fig. 2 Cumulative C storage as a function of depth for four ecosystems. Refer text for the explanation of these patterns.

Source: From Zinke, Stangenberger, et al.^[4]

upper 1 m of soil (Fig. 2). In contrast, a spruce–fir forest contains 50 percent of its soil organic matter in the top 10 cm. There are interesting exceptions to the rule that above-/belowground plant allocation determines soil organic matter distribution patterns in soil. Tropical moist forest soils show a uniform depth distribution similar to the depth distribution of temperate grasslands; however, in tropical forests, this is largely due to a long-term accumulation of recalcitrant organic materials at lower depths in the soil rather than increased allocation to roots. Alpine tundra soils support a largely herbaceous flora but show a similar depth distribution as forest soils because of inhibition of surface litter decomposition by low temperatures and high water saturation.

DECOMPOSITION

Climate

Organic matter decay rates can be related to environmental parameters such as temperature and soil moisture. Climatic indices that correlate well with decay rates include plant moisture and temperature indices,^[21,22] linear combinations of temperature and rainfall,^[23] and actual ET.^[15] Warm temperatures and available soil moisture enhance microbial and micro- and macro-invertebrate activity. These environmental

conditions are also correlated with plant production. As a result, the amount of organic matter present in soil is highest in vegetation types with the highest rates of organic matter production. These are ones found in the warm, moist climate regions. The contours of soil C density displayed in Fig. 1 reflect the balance of input by vegetation production and loss from decomposition imposed by climate. Soil C content increases from lower left to the upper right in Fig. 1 as the temperature decreases in the cool temperate, boreal, and subpolar life zones and as precipitation increases in the warm temperate, subtropical, and tropical life zones.

The combined influence of temperature and precipitation is presented by the third axis of the Holdridge diagram (Fig. 1) as the ratio of potential ET (PET) to annual precipitation. When this ratio is less than 1.0, rainfall exceeds PET and vice versa. Life zones bordering the line with the PET is equal to precipitation (PET ratio = 1.0) have soil C contents around 10 kg m^{-2} except in warm temperate and subtropical zones where strong seasonality limits production, but decomposition conditions are favorable for most of the year. Soil C content increases as the PET ratio decreases, indicating that productivity increases faster than the rate of decomposition with increasing moisture availability.

Organic Matter Quality

On global scale, climate may be the most important factor controlling decay rates, but within a given region, substrate chemistry is the more important factor.^[15,24,25] Decay rate is often negatively related to substrate C/N ratio. Litter C/N is initially much greater than microbial C/N but approaches microbial C/N as the microbes release the C as CO_2 while taking up N (N immobilization). The further the initial litter C/N is from microbial C/N, the slower the decay rate. Lignin content or lignin/N ratios may be better predictors of decay rates because lignin itself is difficult to decompose, and it shields N and other more easily degraded chemical fractions from microbes. Concise and simple models of decay rate are based on a combination of chemical and climatic indices.

The effect of litter quality on soil organic matter content is most dramatically expressed in Podzols (Spodosol in the U.S. Department of Agriculture classification). These occur over large areas in boreal zones dominated by evergreen conifers, but often occur in other regions on shallow or sandy soils. Low N content of organic matter inputs and cool temperatures reduce decomposition and soil animal activity. As a result, large surface organic matter accumulations occur over a thin A horizon. Low temperatures combined with leaching of organic acids result in podsolization as the predominant soil-forming process. Leaching of iron, aluminum oxides, and organic matter results in a distinct E horizon near the surface where these materials are removed and deposited in the

Table 1 Mean organic C contents (kg m^{-2}) by Food and Agriculture Organization–the UN Educational, Scientific and Cultural Organization soil units to 1 m depth.

Soil unit	Mean C (kg m^{-2})
Acrisols	9.4
Cambisols	9.6
Chernozems	12.5
Podzoluvisols	7.3
Ferrasols	10.7
Gleysols	13.1
Phaeozems	14.6
Fluvisols	9.3
Kastanozems	9.6
Luvissols	6.5
Greyzems	19.7
Nitisols	8.4
Histosols	77.6
Podzols	24.2
Arenosols	3.1
Regosols	5.0
Solonetz	6.2
Andisols	25.4
Vertisols	11.1
Planosols	7.7
Xerosols	4.8
Yermosols	3.0
Solochaks	4.2

These soil units generally span a wide range of climate conditions and therefore present a different view of soil organic matter content based on additional soil factors. In particular, the high C content of Podzols, Histosols, and Andisols is apparent. Refer text for additional explanation of biological, chemical, and physical factors responsible.

Source: From Batjes.^[2]

B horizon. If the surface organic layers are included, these soils can have substantial organic matter contents, exceeding the expected amount for the climate conditions. Batjes^[2] gives an average value for Podzols of 24.2 kg m^{-2} for the surface meter, which is considerably above the mean for most other soil types (see Table 1).

SIGNIFICANT PHYSICAL AND CHEMICAL INFLUENCES

There are several notable exceptions to the climate-based explanation of variation in soil C content. There are two in particular that have lower rates of decomposition and therefore higher accumulations of organic matter than expected (Table 1). These include Histosols due to hydrological conditions and Andisols due to parent material chemical effects.

Histosols

In landscape positions where water accumulates at or above the surface of the soil for an appreciable part of the growing season, decomposition can be reduced to such an extent that large amounts of undecomposed organic matter can accumulate. This soil type is called a Histosol and can be found in any region in wetlands where decomposition is restricted. The soil surface of mature or old-growth boreal forests over shallow water tables are often covered with *Sphagnum* moss, which may also lead to the development of Histosols. Histosols with the largest areas and thickest accumulations occur in lowland tundra where a mixture of sedges, lichens, and mosses grow at the northern limit of vegetation in the northern hemisphere. Production, decomposition, and evaporation are limited by low temperatures and water-saturated soils. In these cold regions, deeper layers may freeze and not become thawed during the short growing season (permafrost). As a result, Histosols have C contents over 70 kg m^{-2} in the surface meter (Table 1). Some regions have been accumulating organic matter since the last glacial period without any substantial decomposition. Histosols in such regions may be several meters thick and contain over 250 kg C m^{-2} .^[2] Globally, it is estimated that boreal and subarctic Histosols contain 455 PgC that has accumulated during the post-glacial period.^[26]

Andisols

Andisols form on young volcanic stone (basalt lava) rich in nutrients and alkaline. Andisols are weakly weathered soils associated with pyroclastic parent materials that are rich in allophane, ferrihydrite, and other minerals that readily form complexes with humus molecules. These chemical constituents provide conditions promoting high vegetation production and also the retention of organic matter in soil. As a result, Andisols typically have higher soil C contents (25.4 kg m^{-2} , Table 1) than soils with the same environmental conditions, but different parent materials.

CONCLUSION

Over long periods of time, organic matter in soils is the result of climatic, biological, and geological factors. These factors are not independent. In particular, there exists a strong relationship between climate and vegetation type. In Fig. 1, the Holdridge climate-based life zones have names that depict the dominant vegetation of climates. Jobbágy and Jackson^[27] provide a summary of soil data based on biomes that demonstrates similar soil C distribution as that based on climate (Table 2).

Over shorter periods of time, soil C varies with vegetation disturbances and changes in land use patterns that

Table 2 Mean organic C content (kg m^{-2}) by biome to 1 m depth.

Biome	Mean C (kg m^{-2})
Boreal forest	9.3
Crops	11.2
Deserts	6.2

affect rates of organic matter input and its decomposition. Various land uses result in very rapid declines in soil organic matter from the native condition.^[29–32] Losses of 50% in the top 20 cm and 30% for the surface 100 cm are average. Much of this loss in soil organic C can be attributed to erosion, reduced inputs of organic matter, increased decomposability of crop residues, and tillage effects that decrease the amount of physical protection to decomposition. Evidence from long-term experiments suggests that C losses due to oxidation and erosion can be reversed with soil management practices that minimize soil disturbance and optimize plant yield through fertilization. These experimental results are believed to apply to large regions and that organic matter is being restored as a result of establishment of perennial vegetation, increased adoption of conservation tillage methods, efficient use of fertilizers, and increased use of high yielding crop varieties.^[33,34] Additionally, when agricultural land is no longer used for cultivation and allowed to revert to natural vegetation or replanted to perennial vegetation, soil organic C can accumulate by processes that essentially reversing some of the effects responsible for soil organic C losses initially—from when the land was converted from perennial vegetation—and return them to typical amounts for the climate, vegetation, landscape position, and parent material conditions.^[35,36]

Soil Organic Matter (SOM): Historical Concepts

Christian Feller

Institute of Research for Development, Montpellier, France

Abstract

Soil organic matter (SOM) contributes significantly to the chemical, physical, and biological ecosystem functions of soil. It thus provides agricultural and environmental services, such as soil carbon (C) sequestration, regulation of the water cycle, and detoxification of pollutants. Identification of the functions and services provided by SOM has a long and tumultuous history of scientific discoveries and struggles against false assumptions. This entry reports major steps of this history with emphasis on the role of SOM in: 1) plant productivity, soil fertility, and sustainability of cropping and farming systems and 2) regulating climate change through C sequestration.

INTRODUCTION

The role of soil organic matter (SOM) in controlling the capacity of soil resources to deliver agricultural and environmental services and sustain human societies at both local (e.g., fertility maintenance) and global [e.g., mitigation of atmospheric carbon (C) emissions] scales is scientifically well established. SOM contributes to a range of functions that can be connected to goods and services at the ecosystem level,^[1] but the scientific recognition of this fact and its implications for farming practices and land use management options have fluctuated over time.^[1,2]

This entry presents a brief history of the building of concepts and tools that led to the perception of the interconnection between SOM, soil fertility, and ecosystem sustainability with focus on the following two broad functions of SOM: 1) a productive function, namely, the sustainment of farming and 2) an environmental function, namely, the control of the greenhouse effect, climate change, and soil C sequestration. For more information, see the entry *Soil Organic Matter (SOM): Characterization* (p. 2123).

AGRONOMIC FUNCTION OF SOM

Concepts of plant nutrition varied greatly during antiquity (Browne, 1944).^[1,2] Finally, it was Aristotle's theory that remained influential during the Middle Ages: soil is the main source of nutrients for plants, and soil fertility is dependent on four qualities—warmth, coldness, humidity, and dryness. Some different theories emerged during the 16th and 17th centuries, namely the theory of “salts” from Palissy (1580),^[3] the theory of “water” from Van Helmont

(early 17th century), and the theory of “tillage” from Tull (1733). The idea that the soluble fraction of humus could nourish the plants emerged by the end of the 18th century (Hassenfratz, 1792),^[2] while several authors, founders of the ecophysiology such as Priestley (1777), Ingen-Housz (1780), Senebier (1782), and de Saussure (1804), gave a partial refutation of this theory by experimentally demonstrating a gaseous origin of plant C and the role of light during photosynthesis. Contradictory debates arose on the subject, but many agricultural scientists shared an intermediary point of view and assigned functions in plant nutrition to both SOM and air. This was in particular the view of the famous German agronomist Albrecht Daniel Thaër (1752–1828) known for the “theory of humus” developed in his seminal book *Principles of Rational Agriculture* (1809).^[4]

Thaër's principles were based on the following two unverified theoretical concepts of plant nutrition: 1) the majority of plant dry matter derives from the “soil nutritive juices” contained in the hot water-soluble fraction of soil humus; and 2) plant demand for “juices” is selective and varies with the species cultivated. Therefore, management of soil fertility must be based on the management of the soil-humus balance as well as on that of agricultural techniques and crop succession. The system was completely quantified with an indicator—the “fertility degree”—used for the evaluations of both fertility and economy. Based on a false theory, nevertheless, it was the basis for the first rational and systematic approach to fertilization within the context of sustainable cropping practices (de Wit, 1974).^[2] Thaër's work seriously influenced the thinking of his peers during the first half of the 19th century. Had Thaër focused on mineral rather than organic budgets, he would probably have been regarded as the founder of Western scientific agriculture.

The “mineral theory,” first developed by Sprengel (1838) and then by Liebig (1840) in his authoritative text *Die organische Chemie in ihrer Anwendung auf Agrikultur und Physiologie*, demonstrated the origin of plant dry matter from mineral compounds and not from humus. It was the death of the humus theory and the beginning of mineral fertilization, chemical fertilizer industry, and the “nitrogen–phosphorus–Potassium era.” A practical consequence of this theory is the prevalent idea that organic fertilization is not necessary if mineral fertilizers are available. Grandeau^[5] proposed a theory that bridged the gap between the “humus” and the “mineral” theories by attributing an essential role to humus as a factor of solubilization and thus of assimilation of mineral elements with limited availability for the plant (phosphorus). He created the concept of “bioavailability” that was fully supported by Liebig.^[5] The “mineralist” approach reached its apogee after World War II with a spectacular increase in crop yields and in fertilizer and other input consumptions. However, as early as the 1930s, environmental degradation and loss of ecosystem services appeared: wind and water erosion; air, soil, and water pollution; etc. The notion of a “healthy” function of soil and SOM began to be developed by Balfour and Howard (1940), Balfour (1944), and Rodale (1945). It was the birth of “organic farming” with the partly ideological concept of the biotic pyramid proposed by Albrecht Daniel Thaër (1975): Any soil degradation (at the basement of the pyramid) threatens plant health that threatens animal health and finally human “health.” The philosophy of organic farming is fundamentally holistic. The solutions lie with the abandonment of chemical practices and the predominant use of renewal resources, especially organic matter resources. Organic farming and other agroecological practices are scientifically studied and experimented all around the world in the perspective of a sustainable agriculture: Humus is thus once again in fashion!

AN ENVIRONMENTAL FUNCTION OF SOM: CONTROL OF THE GREENHOUSE EFFECT AND C SEQUESTRATION

Since 1992, increasing attention has been given to the potential of SOM for C storage and to its importance in

the greenhouse gas (GHG) fluxes [mainly carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O)] at the soil–plant–atmosphere interfaces.^[1] The terms “sequestration” and “C sequestration” were proposed to define the aptitude of terrestrial ecosystems to act as sinks for these GHGs. A definition of the “soil C sequestration” including the total balance of the three main GHGs was proposed by Bernoux et al. (2006). The history of “soil C sequestration” (including that of humus or SOM) thus includes those of SOM storage and GHG (especially CO₂) fluxes at different space and timescales. The sole history of CO₂ fluxes is described below.

The first *in situ* measurements of soil CO₂ were made by Boussingault and Lewy (1852, 1853) at depths ranging from 40 to 240 cm. These authors showed that CO₂ concentrations in soils without farmyard manure (FYM) application were 22 to 23 times higher than in the atmosphere and that applying FYM could increase this concentration by 245 times.

The main forerunner to modern CO₂ fluxes measurements at soil–plant–atmosphere level is the Danish ecophysiologist Henrik Lundegårdh (1888–1969; Larkum, 2003). Lundegårdh published considerable data on CO₂ fluxes at the soil–plant interface with two books in 1924 and 1930, respectively, and a vast paper in 1927.^[6]

In these three publications, Lundegårdh reports an impressive amount of quantitative data on *in situ* CO₂ fluxes between atmospheric, plant, and soil components. Data were collected using the instruments of his own conception for the sampling of soil atmosphere (equivalent to our static chamber) or the continuous monitoring of CO₂ fluxes at the plant or atmosphere level. In the 1927 publication, he even described field equipment and experimental designs completely equivalent to “free air CO₂ experiment (FACE),” which are among the most sophisticated experiments for the study of CO₂ fluxes at the field level. Lundegårdh’s findings are remarkably close to the existing data.

CONCLUSION

There is a long history of scientists’ engagement in the study of SOM, as a consequence of their conviction of its

Fig. 1 Ups and downs in the popularity of humus in relation to scientific theories and agricultural practices.

functional value. There are many cases, often forgotten, of perceptions that preview concepts that are accepted as essential for sound management of natural resources, such as that of sustainability (e.g., Thaër) or of developments of new approaches and tools (such as FACE-type experiments) that are readily recognizable by scientists.

The popularity of humus has changed over the past three centuries (Fig. 1), but it is generally accepted by scientists that loss in SOM is one of the major factors, leading to degradation of ecosystem services and loss of ecosystem resilience. In many countries, however, conflicts have arisen between policies for ecosystem protection that embrace sustainable soil management and those targeted at agricultural development. The decision-makers will be convinced by scientists when SOM will be proved to have a quantitative economic value. That is a scientific challenge.

Soil Organic Matter (SOM): Landscape

Henry H. Janzen

Lethbridge Research Centre, Agriculture and Agri-Food Canada, Lethbridge, Alberta, Canada

B.H. Ellert

Agriculture and Agri-Food Canada, Lethbridge, Alberta, Canada

D.W. Anderson

Department of Soil Science, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Abstract

The heterogeneity of organic matter in the landscape and its further rearrangement by human activity determine how ecosystems function. The topsoil, enriched in organic matter, forms a veneer over the landscape, one that varies from place to place and year to year. The performance and persistence of ecosystems depend on this thin layer. And how that layer varies over the landscape, especially in response to management, therefore has long-lasting effects on how productive and resilient the ecosystem will be. We know something about how past management has affected organic matter distribution; we need to learn how restorative practices will shape its patterns across the landscape.

INTRODUCTION

Soil organic matter is composed largely of plant tissues decomposing back to the simple molecules from which they were first formed: carbon dioxide (CO₂), ammonium, water, and various salts. Although often present in large amounts, organic matter is transient—new litter is continually being added, and organic matter already present is always decomposing. So at any time, the amount present reflects the net balance between additions and losses.

Both inputs and losses at a site depend on conditions there. Litter inputs from plant growth and decomposition are both influenced by many factors: temperature, moisture, aeration, nutrients, plant community, and more. And wind and water move organic matter-laden soil about the landscape. So the amount and composition of organic matter differ from place to place in the landscape.

Organic matter varies in several dimensions: It varies vertically within the profile and horizontally across the landscape. It changes across time, often by human influence. How organic matter is distributed over the landscape may be as important as its amount in affecting the way an ecosystem behaves.^[1] In this review, we describe how organic matter is distributed in “natural” landscapes, show how human activities can alter that pattern, and illustrate with a few examples how organic matter distribution (and redistribution) can affect ecosystem function.

ORGANIC MATTER IN LANDSCAPES UNAFFECTED BY HUMAN ACTIVITY

Vertical Distribution

In most soil profiles, organic matter [or organic carbon (C)] concentration is highest near the surface, where most plant litter is added, and then declines with increasing depth.^[2,3] In grasslands, globally, the surface 0.2 m of soil accounts for 42% of the organic C in the first 1 m; in shrublands, the proportion is 33% and in forests, it is 50%.^[4]

The rate of organic matter turnover also changes with depth. Compared to that deeper in the profile, surface soil usually has higher proportions of “young” organic matter from inputs of plant litter. Radiocarbon studies show that the mean turnover time or radiocarbon “age” of organic matter usually increases with depth.^[5–7]

Lateral Distribution

The amount of organic matter in the soil at a given spot is the result of a complex interaction, over time, of parent material, climate, vegetation, and topography.^[8] Among landscapes, at regional scales, organic matter content is controlled largely by precipitation, temperature, soil texture, and vegetation type.^[9,10] But within a landscape, organic matter is also influenced by other factors. Topography, through effects on microclimate and water movement, can produce soils of widely different organic matter

Fig. 1 An illustration of variability in soil organic C in transects across two toposequences, a native grassland and an agricultural field cultivated for about two decades. Organic matter is about 58% C, by weight, so it is often measured as organic C.

Source: Adapted from Gregorich & Anderson.^[11]

within meters (Fig. 1).^[9,12] Usually, the amount of organic matter is lowest near summits and highest in toeslope positions.^[13–15] This pattern occurs for various reasons:^[14,16,17] higher moisture and nutrient status downslope increase litter production; organic matter in lower slope positions may decompose more slowly because of soil conditions (e.g., reduced aeration or accumulated clay); variations in microclimate produce different plant communities across topographical gradients; and erosion may move organic matter downhill.

Apart from topography, localized variations in texture, soil chemistry, vegetation,^[1,18] and other properties may also cause organic matter to vary within landscapes. Even in landscapes that appear uniform, therefore, soil organic matter content varies significantly over scales of several meters. Tiessen and Santos^[19] observed coefficients of variation greater than 50% in organic C and total nitrogen (N) concentrations in the surface soil of a tropical semiarid field ($65 \times 40 \text{ m}^2$) immediately after clearing.

Organic matter varies across landscapes not only in amount but also in form. For example, Paul et al.^[5] observed that radiocarbon “age” of surface soil increased from toeslope to summit positions at two uncultivated grassland sites. And Schimel et al.^[16] found that the relative mineralization rate of organic matter (N mineralized per unit of total N) decreased downslope, even though total mineralization increased, pointing to differences in organic matter quality.

Temporal Distribution

Organic matter in the landscape also changes with time. Soils in early stages of development accumulate organic matter, but the rate of build-up slows as soils approach a steady state, where decomposition roughly balances litter inputs.^[20] Even then, however, organic matter fluctuates during a year because litter additions follow a different pattern from decomposition. It also fluctuates from year to year with changes in weather: in some periods, when litter inputs exceed losses, organic matter accumulates; in others, it is depleted.^[21]

HUMAN INFLUENCE ON DISTRIBUTION

Human activities can profoundly alter soil organic matter content. Historically, disturbance of “natural” ecosystems has almost always resulted in losses.^[22,23] Converting grass- and forestlands to arable agriculture, e.g., typically results in the loss of about 30% of the organic C originally present in the solum.^[24] But with better land management, at least part of the organic matter lost can be restored.^[25]

Human influence on soil organic matter—whether it leads to losses or gains—is rarely uniform over the landscape. Thus, human intervention often alters not only the amount of organic matter, but also its distribution over the landscape. The rearrangement can occur in several ways.

Patchwork Application of Practices

Land practices are often not applied uniformly over the landscape. Forests may be cut in patches; diverse cropping practices may be used in scattered patterns in agricultural landscapes; organic materials such as manures, derived from large, far-flung areas, may be funneled into small areas;^[26] grazing animals may congregate near water or shade, depositing organic matter there.^[27] These, and other practices applied non-uniformly, can redistribute organic matter on the landscape.

Non-Uniform Effects on C Balance

Even where the same management practice or land use change is applied uniformly over a large area, its effect on organic matter may vary from place to place because the landscape is not uniform to begin with. For example, Schimel et al.^[28] observed that proportional losses of organic matter after cultivating grassland were higher in upper- than in lower-slope positions. And the mechanism of organic matter loss, whether by erosion or biological mineralization, may also vary among slope positions.^[11]

Tillage

Farmers cultivate soils to control pests, prepare land for seeding, and bury residues. This tillage dilutes organic

matter-rich soil near the surface by mixing it with soil from deeper layers.^[15] It may also affect organic matter deeper in the profile by altering rooting patterns, leaching, faunal activity, and soil temperature.^[29,30] Consequently, tillage changes organic matter distribution in the profile, even though total amount may not always be affected.^[31]

Tillage also alters lateral distribution of organic matter by physically “dragging” topsoil. Each tillage pass moves soil, but the extent of movement is greater downslope than upslope, so that over the years, tillage moves soil and organic matter to lower-slope positions.^[32]

Erosion

Globally, the predominant human influence on distribution of organic matter in the landscape is via erosion, especially in deforested and agricultural lands. Although erosion is a natural process and occurs also in undisturbed ecosystems, human disturbance may increase erosion by orders of magnitude.^[33,34]

Erosion affects organic matter at a site within the landscape in three ways;^[12] it may remove organic matter; result in mixing of subsoil into the surface layer by stripping surface soil away; or result in deposition of soil eroded from elsewhere in the landscape.

The effects of erosion are not uniform across the landscape. Highest losses usually occur from convex uplands or “shoulder elements.”^[12,14] Much of the eroded soil removed from one location in the landscape may be deposited nearby, especially, in closed watersheds.^[35] But areas of net removal are usually larger than areas of deposition so that erosion often increases the variability of organic matter on the landscape. This is compounded by selective translocation of soil fractions rich in organic matter.^[15,36] The net effect, therefore, is often a removal of organic matter from widespread areas in the landscape and its deposition in low-lying areas.

Erosion not only affects directly the distribution of organic matter on the landscape, but may also have long-lasting secondary consequences through effects on plant growth and litter input.^[15] While erosion can result in extensive translocation of organic matter, its net effect on total amount stored in the landscape is not always clear. If erosion suppresses productivity, thereby limiting replenishment of organic matter, the organic matter may spiral downwards over the long term. But when productivity of eroded areas can be restored, the eroded landscape might eventually contain more organic matter than before, because of the higher storage potential of eroded areas^[37] and the accumulated and buried organic matter in depositional areas.^[15]

Disruption and management of ecosystems by humans often alter irreversibly the amount and distribution of organic matter in landscapes, often increasing variability on the landscape (e.g., Fig. 1).^[38] Our understanding of this redistribution is incomplete.^[39,40]

IMPLICATIONS

The heterogeneity of organic matter in the landscape and its further rearrangement by human activity determine how ecosystems function. To illustrate, we present three examples.

Firstly, the spatial variability of organic matter influences productivity on the landscape. Plant productivity is closely linked to organic matter;^[41] consequently, landscapes with variable organic matter usually show corresponding heterogeneity in productivity (whether high organic matter increases productivity or high productivity increases organic matter is not always clear). In farmlands, therefore, increasing attention has been devoted to “site-specific farming”—adjusting practices spatially to compensate for variability in organic matter and related soil properties.^[42]

Secondly, the way organic matter is distributed across the landscape influences the unintended release of nutrients into the broader environment. For example, organic matter affects transformations of N, both as a source of mineralized N and by effects on microbial activity. Consequently, nitrate leaching or nitrous oxide emissions may be linked to organic matter distribution, especially as sites where organic matter accumulates may also have high moisture.^[43,44]

Thirdly, the heterogeneity of organic matter within the landscape makes it harder to measure changes in C storage. Soil organic matter has been proposed as a potential “sink” for C; widespread adoption of practices that build organic matter could increase C storage in soils, mitigating the increases in atmospheric CO₂ linked to global warming.^[45] But to quantify that “sink” precisely, organic matter distribution across the landscape would have to be taken into account; differences in organic matter among points on the landscape are usually much greater than the expected response to new management.^[46] At one location, Garten and Wullschlegel^[47] estimated that more than 100 samples would need to be taken to detect a change in soil organic C of about 1 Mg C ha⁻¹. The redistribution of organic matter by erosion makes measuring of the C sink even more complicated.^[48] When erosion occurs during the measurement interval, it may be hard to distinguish C exchanged with the atmosphere from that merely redistributed on the landscape.

The topsoil, enriched in organic matter, forms a veneer over the landscape, one that varies from place to place and year to year. The performance and persistence of ecosystems depend on this thin layer. And how that layer varies over the landscape, especially in response to management, therefore has long-lasting effects on how productive and resilient the ecosystem will be. In the past, human activity has often accentuated native variability, removing organic matter from sites where it was already in short supply and depositing it in areas of excess. New approaches may favor the preservation of organic matter both in amount

and distribution across the landscape. We know something about how past management has affected organic matter distribution; we need to learn how restorative practices will shape its patterns across the landscape.

Soil Organic Matter (SOM): Management

R. Cesar Izaurralde

Battelle Pacific Northwest National Laboratory, Washington, District of Columbia, U.S.A.

Carlos C. Cerri

University of Sao Paulo, Sao Paulo, Brazil

Abstract

Soil organic matter (SOM) consists of a complex array of living organisms, such as bacteria and fungi, plant and animal debris in different stages of decomposition, and *humus*—a rather stable brown to black material showing no resemblance to the organisms from which it originates. Because SOM is or has been a part of living tissues, its composition is dominated by carbon (C), hydrogen, and oxygen and—in lesser abundance—by nitrogen, phosphorus, and sulfur among other elements. The levels of SOM are expressed in terms of soil organic carbon (SOC) concentration (g kg^{-1}) or mass per unit area (g m^{-2}) to a given depth. The level of SOC in virgin soils reflects the action and interaction of the major factors of soil formation: climate, vegetation, topography, parent material, and age. These factors control SOC content by regulating the balance between C gains via photosynthesis and losses via autotrophic and heterotrophic respiration, as well as C losses in soluble and solid form. The SOC content usually ranges between 5 and 100 g kg^{-1} in mineral soils. These concentrations appear modest but at 1500 Pg, the amount of organic C stored globally in soils is second only to that contained in oceans and at least twice that found in either terrestrial vegetation or the atmosphere.

INTRODUCTION

Cultivated soils usually contain less soil organic carbon (SOC) than virgin soils^[1] due to the magnification of two biophysical processes: 1) net nutrient mineralization accompanied by the release of carbon dioxide (CO_2) due to microbial respiration and 2) soil erosion. SOC losses of up to 50% have been reported within 30–70 years of land use conversions under temperate conditions.^[2–5] SOC losses reported in subtropical and tropical environments often match or even surpass those observed under temperate conditions.^[6–8] In subtropical and tropical environments, shifting cultivation systems appear to conserve more SOC than forestlands permanently cleared for cultivation.^[9]

MAJOR PROCESSES LEADING TO CARBON (C) LOSSES FROM SOIL

Mineralization Processes

Depending on its frequency and kind, tillage changes the soil biophysical environment in ways that affect the net mineralization of nutrients and the release of C. These changes can be described in terms of increases or decreases in soil porosity, disruption of soil aggregates,

and redistribution in the proportion of soil aggregate size, as well as alteration of energy and water fluxes. All these changes enhance, at least temporarily, the conversion of organic C into CO_2 ^[10] and the net release of nutrients from soil organic matter (SOM). Much of the success of past agricultural practices relied heavily on the control of decomposition processes through tillage operations to satisfy plant nutrient demands. All these came at a price, however, for a heavy reliance on soil nutrients to feed crops without proper replenishment led to the worldwide declines of SOM.^[11]

Soil Erosion Processes

Agricultural ecosystems normally experience soil losses at rates considerably greater than natural ecosystems because of an incomplete plant or residue cover of the soil during rainy or windy conditions. When surface and environmental conditions are right (i.e., bare soil, sloping land, intense rain, and windy weather), the kinetic energy embedded in wind and water is transferred to soil aggregates causing them to be detached and transported away from their original position across fields or downhill. Besides the physical loss of soil particles and on-site impact on soil productivity, the detachment and transport processes also cause aggregate breakdown, thereby exposing labile C to microbial

activity. This aggregate breakdown also facilitates the preferential removal of soil materials comprised mainly of humus and clay or silt fractions. Consequently, water- and wind-borne sediments become enriched in C with respect to the contributing soil. C enrichment ratios ranging from 3 to 360 have been reported.^[12,13] The fate of these C-enriched sediments is not well known, for while transport and burial of C in eroded sediments may lead to “sequestration,”^[14] it may also result in part of it being emitted back to the atmosphere as CO₂.^[15]

RESTORING SOM: THE EMERGING SCIENCE OF SOIL C SEQUESTRATION

The Role of Long-Term Field Experiments

SOM is an essential attribute of soil quality^[16] and has an essential role in soil conservation and sustainable agriculture. Many practices—some involving land use changes—have been shown to increase SOM and thus received considerable attention for their possible role in climate change mitigation.^[17–19] C sequestration in managed soils occurs when there is a net removal of atmospheric CO₂ because C inputs (non-harvestable net primary productivity) are greater than C outputs (soil respiration, C costs related to fossil fuels and fertilizers). Soil C sequestration has the additional appeal that all its practices conform to the principles of sustainable agriculture (e.g., reduced tillage, erosion control, diversified cropping systems, improved soil fertility). Long-term field experiments have been instrumental to increase our understanding of SOM dynamics.^[20,21] The first and longest standing experiment was started at Rothamsted, England, by J.B. Lawes and J.H. Gilbert who in 1843 began documenting the impact of nutrient manipulation on crop yields and soil properties.^[22]

Other experiments were initiated thereafter in the United States, Europe, and Oceania with the goal of discovering interactions among climate, soil, and management practices. The knowledge that emerged from these experiments has been instrumental for the development and testing of agroecosystem and SOM models.^[23]

The Global Importance of Soil C Sequestration

There appears to be a significant opportunity for managed ecosystems to act as C sinks; e.g., results from inverse modeling experiments suggest that during 1988–1992, terrestrial ecosystems may have been sequestering atmospheric C at rates of 1–2.2 Pg y^{−1}.^[24] Some of the likely causes include the growth of new forest in previously cultivated land^[25] and the “CO₂ fertilization effect.”^[26] Globally, agricultural soils have been estimated to have the capacity to sequester C at a rate of 0.6 Pg y^{−1}^[11] during several decades. The realization of this potential C sequestration would not be trivial since it would offset roughly

about one-tenth of the emissions from fossil fuels. In the United States, annual gains in soil C from improved agricultural practices have been estimated at 0.14 Pg yr^{−1}.^[25] Whether or not soil C sequestration practices are widely adopted will depend on their value relative to other C capture and sequestration technologies.

Mechanisms of Soil C Sequestration

Reviews of experimental results have contributed to organize our understanding of the environmental and management controls of soil C sequestration in grassland^[27,28] and agricultural^[29,30] ecosystems. The use of C balance, soil fractionation, and isotope techniques have been instrumental to reveal how new C (from crop residues, roots, and organic amendments) enters soil, resides shortly (for a few years) in labile soil fractions, and finally becomes a long-time constituent (for hundreds of years) of recalcitrant organo-mineral complexes.^[31] Fig. 1 contrasts young

(labile) organic matter fractions extracted from two cultivated soils with and without nitrogen (N) fertilizer.^[32] The amounts of labile organic matter—fine roots and other organic debris—present in each soil reflect differences in crop productivity induced by the addition of N at annual rates of 50 kg ha⁻¹ for 13 years. “Terra Preta” soil—in tropical regions of South America and West Africa—represents a prime example of ancient wisdom applied to develop sustainable agriculture through the improvement of soil fertility and SOM.^[33]

The quantity and quality of C entering soil as well as the interaction of this C with the soil biophysical environment are major factors determining the rate and duration of soil C sequestration. The quantity of C added to soil in the form of roots, crop residues, and organic amendments has been shown to play a dominant role in defining the trajectory of SOC over time.^[34] Management practices geared toward optimizing nutrient supply and building nutrient reserves (e.g., fertilization and the use of legumes in crop rotations) are almost guaranteed to increase soil C stocks. The quality of crop residues and the timing of their incorporation to soil also have an influential role on C decomposition and, thus, on soil C storage.^[35] The degree of soil disturbance—through its impact on soil aggregation—constitutes another major factor regulating C decomposition and retention in soil.^[36] In this context, no tillage agriculture has come to represent one of the most significant technological innovations of the last years because it allows farmers the possibility of growing crops economically while reducing erosion and improving both quantity and quality of SOM. A few examples of the management impacts on soil C sequestration from around the world are presented in Table 1.

SOM, Energy, and Full C Accounting

Land is the natural habitat of humans. Humans dwell on it and use it as a resource for the production of food, fiber, and other goods. Simply put, land is managed when there is manipulation of energy and matter flows in order to meet certain economic and social objectives. Farm mechanization and fertilizers are two of the many technical innovations that—though they rely on the utilization of fossil energy—have brought dramatic increases in food production during the 20th century. Changes in management practices that include soil C sequestration as an objective require careful evaluation of their impact not only on soil C gains but also on C costs from the use of fossil energy (e.g., manufacture of fertilizers)^[46,47] and on the net greenhouse gas emissions.^[48]

THE ROLE OF SOM IN THE 21ST CENTURY

SOM has played and will continue to play a central role in sustainable land management. The restoration of SOM at

global scales offers a unique opportunity to mitigate global warming. As population levels and affluence increase, demands on land to produce food, fiber, biomass, and other products will remain high. Because land is finite, important decisions will have to be made in order to balance such demands with functional objectives such as the preservation of natural ecosystems. As part of any climate policy, the impact of land use changes and management on SOM storage should be included as a criterion for making these decisions. Depending on their degree of expansion, several evolving agricultural technologies—such as genetically modified crops, conservation tillage, organic farming, and precision farming—may have important implications for soil C sequestration.^[19] Their ultimate impact on C sequestration will depend not only on the economic benefit realized by individual producers but also on whether society recognizes the value of soil C storage to mitigate global warming.

Abstract

Considered a general purpose tool for characterization of samples at the molecular level in environmental and life sciences, mass spectrometry (MS) is commonly used for measuring organic matter in air, water, and soil. Broad base of commercially available instrumentation and data analysis tools provide functional analytical platforms for molecular characterization for a variety of applications and samples. MS instrumentation with ultrahigh-resolving power ($m/\Delta m_{\text{FWHM}} > 200,000$) is necessary for broad identification of thousands of molecular components present in organic matter samples. This entry discusses basic principles of data analysis for ultrahigh-resolution MS measurements of small molecules of organic matter.

INTRODUCTION

Elemental composition analysis of natural organic matter (NOM) has a broad set of applications in agriculture, environment, energy, human health, forensics, and warfare, just to name a few. Regardless of whether the objective is broad elemental composition characterization or targeted inquiry for chemical or biomarkers, mass spectrometry (MS) is becoming the dominant analytical platform for rapid survey of NOM at the molecular level. Bibliometric study of MS usage in research articles over the last three decades from 1980 to 2010 of analytical chemistry shows trends of sharp increase across wide range of scientific disciplines including earth and environmental sciences.^[1] Each “omics” conquest by MS strengthens analytical capabilities of MS through development of new methods, instrumentation, and computational tools. Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR MS) is the MS platform offering the highest mass resolving power and accuracy, allowing unique determination of elemental composition from mass measurement alone, for small (<500 Da) organic molecules.^[2]

NOM samples differ in source (atmosphere, hydrosphere, and geosphere), complexity (water, sediments,

aerosol, permafrost, agricultural soil, petroleum, etc.), and applied extraction methods (liquid solvents, ionic liquids, and supercritical fluids) all of which can influence selection for combining chromatography, MS instrumentation, and ionization methods for deeper analyte coverage. Electrospray ionization (ESI) coupled with FT-ICR MS is the optimal and most utilized technique for NOM analysis; a review by Sleighter and Hatcher^[3] offers more detailed information on ionization methods, application of positive and negative ion modes, and interpretation of MS spectra from NOM samples.

DATA PROCESSING OF ULTRAHIGH MASS SPECTRA

Mass spectrometers work by measuring changes in ion current due to fundamental ion properties, i.e., mass, charge, and abundance, resulting in an ion mass-to-charge ratio (“m/z”) and count (intensity) pair. A mass spectrum is a 2-D plot correspondent to measured ions m/z and intensity pairs, commonly referred as peaks. Thousands of peaks representing different molecular species could be measured and identified in a single ESI FT-ICR spectrum from NOM

Fig. 1 Negative mode mass spectra from 12T FT-ICR instrument from mud pore water with more than 7,000 resolved peaks in m/z range 200–1,000 with signal-to-noise better than 5 and average peak resolution of 310,000. Inset illustrates distance and precision at which isotopic peaks are located from the mono-isotopic peak.

sample as illustrated in Fig. 1. Measuring samples in both positive and negative ion mode significantly increases coverage for NOM samples that usually contain both basic and acidic molecular species preferentially ionized in the positive and negative modes, respectively. Positive mode spectra are more complex as they contain both hydrogen (H_2) and sodium adducts, making them more challenging for interpretation, i.e., chemical formula assignment. Instrument manufacturers usually provide specialized software functions for low-level signal processing as well as graphical spectrum annotation tools. Preparing the instrumentation for MS experiment according to the “best practice” guide^[4] requires external calibration of the mass spectrometer using standard mixtures as close in time as possible to the actual sample measurements. This is a

necessary step for testing of instrument performance and stability. After low-level peak picking, a list of peaks is internally calibrated to assure necessary mass measurement accuracy (MMA) for molecular formula assignment. Careful and accurate execution of these steps is of paramount importance; missteps at this stage could invalidate or provide misleading results and conclusions. Fortunately, NOM samples often contain known classes of compounds (humics, fatty acids, metabolic products, and contaminants) ideal for targets of internal calibration over wide m/z range. Once m/z values are calibrated to sub-ppm error values, the molecular formula assignment procedure can start. Most data analysis workflows start with low m/z values where unique formula assignments are possible and then extend the formula to higher m/z values based on expected

Fig. 2 Assigned molecular formula with mass error within 0.5 ppm at nominal peak 283 using CIA software for spectrum in Fig. 1. In total, more than 5,900 (~84%) molecular formula including isotopic ^{13}C peaks are assigned. Inset shows mass error distribution for assignment across full range.

relationships in the composition of NOM mixture. Adding basic building blocks [methylene (CH_2), H_2 , oxygen (O), etc.] on already assigned formula, amounts to precisely evaluating spacing between peaks and minimizes the necessity for direct formula assignment. This technique of “formula propagation” using basic building blocks is best illustrated using plots exploring the concept of Kendrick mass and defect (KMD) analysis.^[5] Briefly, Kendrick mass is a scaling transformation such that CH_2 assumes integer mass 14 [instead of IUPAC (International Union of Pure and Applied Chemistry) mass of 14.01565] and mass defect 0. Literally, Kendrick mass transformation straightens skewed IUPAC mass defect plots for formulae differing by CH_2 into easily identifiable horizontal lines (Fig. 3A). This simple transformation allows visual analysis of related compound classes based on heteroatom composition and spotting of isolated outlier “identifications,” leading Marshall and coworkers to propose adoption of 2-D KMD plots as standard visualization technique when presenting results from NOM measurements.^[8] Extension of the method using higher order of mass defect analysis was proposed by Roach et al. allowing resolution of compounds with close KMD due to secondary and tertiary compositional differences.^[9]

Measuring organic matter is related to understanding and modeling dynamics of carbon (C) cycling that necessitates increased throughput and automation of data analysis steps. Compound identification algorithm (CIA) developed by Kujawinski and Behn^[10] at Woods Hole Oceanographic Institute is the only general, fully implemented, automated, and freely available formula assignment software for organic matter from high-resolution mass spectra. CIA, implemented in Matlab (MathWorks) programming environment, relies on sub-ppm MMA of FT-ICR MS spectra and precalculated database of molecular formula comprising of

elements C, H, nitrogen (N), O, phosphorus (P), and sulfur (S). The database includes molecular formulae in range of 150–1,500 Da compiled according to “seven golden rules” for filtering chemically plausible molecular formula.^[11] Relationships between peaks are established based on common functional groups and building blocks (CH_2 , H_2 , and O, extendable to others). Formula assignment starts from low m/z range and search for database matches with 1 ppm MMA, if peak assignment is not already established based on relationship with other peaks through specified basic building blocks. In case of ambiguity formula, selection is based on lowest number of non-oxygen heteroatoms N, S, and P. Tuning of algorithm using non-oxygen heteroatom filters and selected formula propagation rules based on prior knowledge about sample or extraction protocols could reduce false positive assignments; for example, limiting numbers of N and S atoms in aerosol samples or requiring certain number of O atoms for each P in soil samples. Algorithm is independent of MS instrumentation, supports both positive and negative ion mode, and includes alignment between different spectra for robust estimation of spectral similarity. CIA is available through source code public repository GitHub.^[10] Replacing universal CIA database with specialized databases tailored for particular NOM samples, e.g., petroleum, lignin, or metabolome, should be in a straightforward manner, offering opportunity for both more confident and faster formula assignments.

RESULTS INTERPRETATION AND VISUALIZATION

Once MS peaks are assigned with molecular formulae, the interpretation of results represents its own challenges. Various indexes based on elemental composition counts

Fig. 3 Kendrick mass defect (A) and van Krevelen (B) plots are most utilized diagrams for interpretation of NOM results from MS measurements. Based on spectrum in Fig. 1, mass defect plot illustrates homologous series represented with straight lines. In van Krevelen plot, expected location of biomolecule classes is indicated with overlaid shapes.

Source: Compiled from Sleighter & Hatcher,^[3] Mann, Chen, et al.,^[6] and Van Krevelen.^[7]

and ratios are used to introduce fuzzy structural information, categorize results, and draw research conclusions. Double-bond equivalent or rings-plus-double-bond equivalent is an established index calculated directly from molecular formula to describe unsaturation and rings in molecule and is often presented in research articles plotted against C-number or H:C ratio.^[11] Similarly, aromaticity index is developed as an identification measure for aromatics and condensed aromatics based on their density of double C–C bonds obtainable from molecular formula.^[12] CHO index is constructed on the concept of oxidation state of organic C offering a better measure of NOM degradation potential.^[6] Some plot variants of these indexes are often found in MS-based NOM research manuscripts, but it would be unusual to find one without a visual representation using van Krevelen diagram. Although initially developed for assessment of structures and processes in various coal samples, van Krevelen diagram^[7] became an unavoidable tool for graphical interpretation of formula assignments from NOM samples. Original van Krevelen diagrams display 2-D plane scatter plots of molecular formulae with X,Y axis measuring O:C and H:C ratios, respectively. Application of van Krevelen diagram on general NOM samples led to mapping of regions of the diagram plane to different classes of organic compounds (Fig. 3B), providing useful insight into NOM structural characteristics.^[13] Three-dimensional variation of the plots was proposed by adding N:C ratio as an additional coordinate axis, effectively allowing visual separation of assigned formula according to the O and N classes.^[14]

CHALLENGES, PROSPECTS, AND FUTURE DIRECTIONS

Quantitative analysis of sample absolute abundance is one of the longest standing challenges with ESI-MS application to complex samples due to the vast differences in ionization efficiencies of analyte components. At the moment, ESI-MS is considered a non-quantitative measure for characterization of complex mixtures, i.e., measured signal intensity does not correlate in a simple or well understood manner with actual analyte concentrations in sample due to the charge competition in electrospray. Most of the attempted solutions propose calibration of ionization sensitivity based on standard, e.g., organic acids, introduced together with analyte; however, since signal suppression occurs in the ionization stage, this approach offers questionable results.

Another serious disadvantage of MS as standalone platform is that MS instrumentation cannot obtain structural information for isomeric ions from a shotgun MS experiment. In tandem mass spectrometry (MS/MS), the parent molecule with a narrow m/z range is fragmented in a secondary MS event using miscellaneous dissociation

methods. The collected fragment ions are then used to infer parent molecule structural information. Application of MS/MS is mostly limited to specialized NOM components like lipids or metabolome products where isolation of ions for fragmentation is not as challenging as for general NOM samples.^[3] Using nuclear magnetic resonance (NMR) in conjunction with MS is suggested as the ultimate technique when full structural information is required; however, at the moment, it lacks throughput for broad NOM characterization, again due to complexity of typical NOM samples. Structural determination by NMR would require deep fractionation of the NOM sample to reduce the number of organic molecules present.

Advancement in FT-ICR instrumentation with higher magnetic fields (two 21T FT-ICR systems are at preproduction in National High Magnetic Field Laboratory in Tallahassee, Florida, U.S.A., and Pacific Northwest National Laboratory, Richland, Washington, U.S.A.) will offer even higher sensitivity and necessary resolving power for going significantly higher than 500 Da boundary for unique elemental composition determination from mass only, set by Kim, Rodgers, and Marshall.^[2] Novel computational tools based on these spectra are expected to make use of fine isotopic structure resolving ambiguities and allowing deeper coverage and direct formula assignments to challenging classes of important environmental components such as organometallics. With growing interest of the research community, one can expect continuous technology advances as well as the construction of MS spectral libraries with searchable metadata information allowing comparison of NOM across geochemical, ecosystem, and temporal gradients. Accumulated knowledge and computational infrastructure will contribute to building better diagnostic and predictive models of the C cycle feedback loops to climate, facilitating resolution of pressing sustainable use of resources and climate change challenges.

CONCLUSION

Ultrahigh resolution MS provides a general purpose analytical platform for wide characterization of organic matter in complex environmental samples. Sub-ppm MMA allows direct molecular formula assignment for small NOM molecules, an important step for better understanding of sample composition and reactivity. Utilization of fragmentation methods and isotopic signatures should further increase reliability of formula assignments and provide insights into NOM structural properties. An ever increasing volume of acquired data presents both challenges and opportunities for development of new data mining algorithms and visualization functions. Continuous advances in FT-ICR instrumentation, extraction protocols, ionization and fragmentation methods, and data processing tools will increase the utilization of ultrahigh-resolution MS in soil and other environmental sciences.

ACKNOWLEDGMENTS

We want to acknowledge Kelly Wrighton from the Ohio State University for providing samples for MS measurements used in figures. MS measurement was performed using EMSL, a DOE Office of Science User Facility sponsored by BER and located at Pacific Northwest National Laboratory (PNNL). PNNL is operated by Battelle for Department of Energy.

Soil Organic Matter (SOM): Modeling

Peter Smith

*Institute of Biological and Environmental Sciences, School of Biological Sciences,
University of Aberdeen, Aberdeen, Scotland*

Abstract

There are a number of approaches to modeling soil organic matter turnover including: 1) process-based multicompartment models; 2) models that consider each fresh addition of plant debris as a separate cohort which decays in a continuous way; and 3) models that account for carbon and nitrogen transfers through various trophic levels in a soil food web. These approaches are described in more detail below.

PROCESS-BASED, MULTICOMPARTMENT SOM MODELS

Most models are process based, i.e., they focus on the processes mediating the movement and transformations of matter or energy and usually assume first order rate kinetics.^[1] Early models simulated the SOM as one homogeneous compartment.^[2] Some years later, two-compartment models were proposed^[3,4] and, as computers became more accessible, multicompartment models were developed.^[5,6] Of the 33 SOM models represented within the Global Change and Terrestrial Ecosystems (GCTE) Soil Organic Matter Network (SOMNET) database,^[7–9] 30 are multicompartment, process-based models. Each compartment or SOM pool within a model is characterized by its position in the model's structure and its decay rate. Decay rates are usually expressed by first-order kinetics with respect to the concentration (C) of the pool

$$dC/dt = -kC$$

where *t* is the time. The rate constant *k* of first-order kinetics is related to the time required to reduce by half the concentration of the pool “when there is no input.” The pool's half-life [*h* = (ln 2)/*k*], or its turnover time (*τ* = 1/*k*) are sometimes used instead of *k* to characterize a pool's dynamics: The lower the decay rate constant, the higher the half-life, the turnover time, and the stability of the organic pool.

The flows of C within most models represent a sequence of carbon going from plant and animal debris to the microbial biomass and then to soil organic pools of increasing stability. Some models also use feedback loops to account for catabolic and anabolic processes and microbial successions. The output flow from an organic pool is usually split. It is directed to a microbial biomass pool, another organic pool, and, under aerobic conditions, to CO₂. This split simulates the simultaneous anabolic and catabolic activities and growth of a microbial population feeding on one

substrate. Two parameters are required to quantify the split flow. They are often defined by a microbial (utilization) efficiency and stabilization (humification) factor which control the flow of decayed C to the biomass and humus pools, respectively. The sum of the efficiency and humification factors must be inferior to one to account for the release of CO₂. A thorough review of the structure and underlying assumptions of different process-based SOM models is available.^[6]

COHORT MODELS DESCRIBING DECOMPOSITION AS A CONTINUUM

Another approach in modeling SOM turnover is to treat each fresh addition of plant debris into the soil as a cohort.^[5] Such models consider one SOM pool that decays with a feedback loop into itself. For example, Q-SOIL^[10] is represented by a single rate equation. The SOM pool is divided into an infinite number of components, each characterized by its “quality” with respect to degradability as well as impact on the physiology of the decomposers. The rate equation for the model Q-SOIL represents the dynamics of each SOM component of quality *q* and is quality dependent. Exact solutions to the rate equations are obtained analytically.^[11]

FOOD-WEB MODELS

Another type of model simulates C and N transfers through a food web of soil organisms,^[1,12] such models explicitly account for different trophic levels or functional groups of biota in the soil.^[13–18] Some models that combine an explicit description of the soil biota with a process-based approach have been developed.^[19] Food-web models require a detailed knowledge of the biology of the system to be simulated and are usually parameterized for application at specific sites.

Table 1 Overview of SOM models represented within GCTE-SOMNET in January 2001.

Inputs								
Model	Timestep	Meteorology	Soil and plant	Management	Factors affecting decay rate constants		Soil outputs	References
ANIMO	Day, week, month	P, AT, Ir, EvW	Des, Lay, Imp, Cl, OM, N, pH	Rot, Ti, Fert, Man, Res, Irr, AtN	T, W, pH, N, O		C, N, W, ST, gas	[20]

FACTORS AFFECTING SOM TURNOVER IN MODELS

Rate “constants” (k) are constant for a given set of biotic and abiotic conditions. For non-optimum environmental circumstances, the simplest way to modify the maximum value of k is by multiplication by a reduction factor μ —ranging from 0 to 1. Environmental factors considered by SOM models include temperature, water, pH, nitrogen, oxygen, clay content, cation exchange capacity, type of crop/plant cover, and tillage.

Many studies show the effect of temperature on microbially mediated transformations in soil, either expressed as a reduction factor or the Arrhenius equation; but the assumption that SOM decomposition is temperature dependent has been challenged by a study suggesting that old SOM in forest soils does not decompose more rapidly in soils from warmer climates than in soils from colder regions.^[53] Studies, however, suggest that old SOM is not more resistant than younger pools of SOM.^[54,55] Water and oxygen have a major impact on the microbial physiology. While some models simulate O_2 concentrations in soil explicitly,^[56,57] many define the extent of anaerobiosis based on soil pore space filled with water.^[58,59] Soil clay content and total SOM are correlated. Various schemes simulate the effect of clay on rate equations to obtain SOM accumulation. Nitrogen is an essential element for microbial growth that will be maximal when enough N is assimilated to maintain the microbial C:N ratio.^[60] An overview of the 33 models represented in the GCTE-SOMNET,^[7,8] including the factors affecting SOM turnover that are presented in Table 1.

SOM MODEL EVALUATION

There are many reasons for evaluating the performance of a SOM model. Model evaluation shows how well a model can be expected to perform in a given situation, it can help to improve the understanding of the system (especially where the model fails), it can provide confidence in the model's ability to predict changes in SOM or where there are no data, and it can be used to assess the uncertainties associated with the model's predictions. Models can be evaluated at a number of different levels. They can be evaluated at the individual process level, at the level of a subset of processes (e.g., net mineralization), or the model's overall outputs (e.g., changes in total SOM over time) can be tested against measured laboratory and field data. Models can also be evaluated for their applicability in different situations, e.g., for scaling-up simulated net C storage from a site specific to a regional level.^[61] Many examples of different forms of SOM model evaluation are presented elsewhere.^[6]

In the most comprehensive evaluation of SOM models,^[61] nine models were tested against 12 data sets from

Fig. 1 Overall root mean square error value for nine SOM models when simulating changes in total soil organic carbon in up to 12 data sets from seven long-term experiments. The RMSE values of the models with the same letter (a or b) do not differ significantly (two sample, two-tailed t-test; $p > 0.05$), but the RMSE values of the two groups (a and b) do differ significantly (two sample, two-tailed t-test; $p < 0.05$).

Source: From Smith, Smith, et al.^[62]

seven long-term experiments representing arable rotations, managed and unmanaged grassland, forest plantations, and natural woodland regeneration. The results showed that six models had significantly lower overall errors [root mean square error (RMSE)] than another group of three models (Fig. 1).

The poorer performance of three of the models was related to failures in other parts of the ecosystem models, thus providing erroneous inputs into the SOM module.^[61]

SOM MODEL APPLICATION

SOM models are often used as research tools in that they are hypotheses of the dynamics of C and N in soil and can be used to distinguish between competing hypotheses.^[41] Another increasing application of SOM models is in agronomy; many SOM models are being used to improve agronomic efficiency and environmental quality through incorporation into decision support systems, e.g., SUN-DIAL-FRS,^[48] DSSAT,^[27] and APSIM.^[21]

SOM models are being used, more than ever, to extrapolate our understanding of SOM dynamics both temporally (in to the future) and spatially (to assess C fluxes from whole regions or continents). An early example of a regional scale application was the use of the CENTURY model to predict the effects of alternative management practices and policies in agroecosystems of the Central United States.^[63] Since then, many studies have adopted similar methodologies to assess SOM dynamics at the regional,^[64] national,^[65,66] and global scales.^[67–75] SOM models are increasingly being used by policy makers at the national, regional, or global scales, e.g., in the post-Kyoto

debate on the ability of the terrestrial biosphere to store carbon.^[76] With such an important role in society, it is important that SOM models are transparent, well evaluated, and well documented. There is still a variety of understanding and different hypotheses incorporated in our SOM models. The developments in SOM models will further improve our understanding and allow models to be used truly predictively, without the need for site-specific calibration. These developments will improve estimates of, and reduce, the uncertainty associated with SOM model predictions.

CONCLUSION

SOM models are used for many purposes in soil science, including use as tools to synthesize and explore, explain, and extrapolate experimental data, use for making projections of SOM behavior under environmental conditions, and use for supporting decision making at many levels, by many users. SOM models is one of our most important tools for improving our understanding soil of organic matter dynamics.

Soil Organic Matter (SOM): Molecular Simulations

Amity Andersen

Pacific Northwest National Laboratory, Richland, Washington, U.S.A.

Abstract

Molecular simulation is a powerful tool used to gain an atomistic, molecular, and nanoscale level understanding of the structure, dynamics, and interactions from adsorption on minerals and assembly in aggregates of soil organic matter (SOM). Given the importance of SOM fate and persistence in soils and the current knowledge gaps, applications of atomistic scale simulations to study the complex compounds in SOM and their interactions in self-assembled aggregates composed of different organic matter compounds and with mineral surfaces of different types common in soils are few and far between. Here, we describe various molecular simulation methods that are currently in use in various areas and applicable to SOM research, followed by a brief survey of specific applications to SOM research and an illustration of our recent efforts in this area. We conclude with an outlook and the challenges for future research in this area.

INTRODUCTION

A number of molecular simulation methods have been developed to give atomistic and molecular-scale insight in several fields of research including chemistry, biology, biotechnology, solid- and liquid-state physics, and materials science. These cross-cutting techniques can also be applied to modeling efforts in soil science.^[1] The application of molecular simulation methods to soil organic matter (SOM) has been limited, but such methods can provide considerable insight into the molecular structure, dynamics, and processes of SOM including interactions with water, mineral surfaces, ionic species, and other soil organics.

MOLECULAR SIMULATION METHODOLOGIES

These methods can be divided into three broad categories: classical, quantum mechanical, and mixed classical/quantum mechanical methods.

Classical Molecular Mechanics Methods

The term “classical” implies the use of classical Newtonian physics to describe the interactions and motion of the atoms when conducting this class of molecular simulations. In these methods, the atomic interactions, Coulombic (electrostatic), van der Waals, bonding, angles, and dihedral and improper torsion angles are effectively accounted for with empirically or quantum-mechanically derived classical force field parameters. Validated force field parameter sets are widely available to simulate biomolecular/organic systems [e.g., assisted model building with energy refinement (AMBER),^[2] Chemistry at HARvard Macromolecular Mechanics,^[3] optimized potentials for

liquid simulations,^[4] GRONingen MACHine for Chemical Simulations (GROMACS),^[5] generalized AMBER force field,^[6] and condensed-phase optimized molecular potentials for atomistic simulation studies^[7]], inorganic mineral systems (e.g., ClayFF force-field^[8]), and hybrid organic–inorganic systems (e.g., INTERFACE^[9]). Since water is typically present, water force field models are also important (e.g., extended simple point charge model,^[10] 3-site transferable intermolecular potential model,^[11] and 4-site transferable intermolecular potential model^[11]). A representative energy function describing the various atomistic interactions, for instance, in the AMBER force field^[2] is shown in Eq. 1:

$$\begin{aligned} V(r) = & \sum_{\text{bonds}} k_b (d - d_0)^2 + \sum_{\text{angles}} k_a (\theta - \theta_0)^2 \\ & + \sum_{\text{torsions}} \sum_n \frac{1}{2} V_n [1 + \cos(n\omega - \gamma)] \\ & + \sum_{j=1}^{N-1} \sum_{i=j+1}^N f_{ij} \left\{ \epsilon_{ij} \left[\left(\frac{r_{0ij}}{r_{ij}} \right)^{12} - 2 \left(\frac{r_{0ij}}{r_{ij}} \right)^6 \right] \right. \\ & \left. + \frac{q_i q_j}{4\pi\epsilon_0 r_{ij}} \right\} \end{aligned} \quad (1)$$

The first term on the right side describes the harmonic (spring-like) motion of the molecular bonds (two-atom interactions). The second term describes the harmonic motion of the bond angles (three-atom interactions). The third term describes the motion of the torsion angles (four-atom interactions). The fourth term describes the non-bonding Lennard–Jones-type potential for the van der Waals interaction of two atoms and the Coulombic (electrostatic) pair-wise interactions, respectively. Other force fields may have additional interaction terms describing the

coupling of various internal variables such as angles and bond lengths. From a point of view of the computational methods described in this entry, classical molecular dynamics methods are the least demanding computationally since the complex interaction between atoms is described with a simple effective potential as described earlier. Simulations with millions of atoms can be performed on state-of-the-art supercomputers using this approach.^[12] Such simulations also include water-solvated DNA and RNA segments and small proteins interacting with clay mineral surfaces.^[13–19] Most force fields are not able to simulate chemical reactions. The ReaxFF force field of Goddard et al.^[20] is a force field that is designed to model chemical reactions. However, the parameterization of the ReaxFF force field to handle possible SOM reactions is unavailable and may take considerable effort, given the complexity of such systems. Course-graining strategies are also available to group atoms into functional groups with effective potentials to further reduce the number of particles (i.e., atoms), thereby reducing the computational cost of the simulation. Approaches to extend the simulation timescales beyond what can be accomplished with typical molecular dynamics simulations are also available.

Software packages available to perform classical molecular dynamics simulations of SOM and its interactions with minerals include large-scale atomic/molecular massively parallel simulator (LAMMPS),^[21] NANoscale Molecular Dynamics,^[22] GROningen MACHine for Chemical Simulations (GROMACS),^[5] Daresbury Laboratory (DL)_POLY,^[23] and many others (e.g., see http://en.wikipedia.org/wiki/List_of_software_for_molecular_mechanics_modeling).

Quantum Mechanical Methods

Quantum mechanical or quantum chemistry methods are more complex and go far beyond the simple force field description of the atomic interactions and motion found in the classical methods. These methods use quantum mechanical or first-principles techniques to describe the behavior of the electrons and nuclei. Chemical bonding, reactions, and charge transfer processes are naturally described with this approach. These methods involve solving the Schrödinger equation given by,

$$\hat{H}\Psi = E\Psi \quad (2)$$

where E is the total energy of the system, Ψ is the wave function, and $\hat{H}$, the Hamiltonian, is expressed as:

$$\hat{H} = \sum_i -\frac{\hbar^2}{2m_e} \nabla^2 \mathbf{r}_i + V_{\text{ext}}(\{\mathbf{R}_I\}) + V_{e-e}(\{\mathbf{r}_i\}) \quad (3)$$

for the many-body system with the first term describing the electronic kinetic energy, the second term describing the electron–nuclei interactions, and the third term describing

the electron–electron interactions. Quantum chemistry methods are further divided into two categories: *ab initio* (or first principles) and semiempirical. The *ab initio* methodologies include, in increasing degree of complexity and computational expense, Hartree–Fock theory, density functional theory (DFT), Møller–Plesset perturbation theory, coupled-cluster theory, and configuration interaction. Semiempirical methodologies, which are less accurate than the *ab initio* methods, include modified intermediate neglect of differential overlap, Austin Model 1, Parameterized Model 3, and density functional tight-binding (DFTB). The above list of *ab initio* and semiempirical methods is not exhaustive but serves as a starting point for further reading.^[24,25] For the size of systems encountered in SOM, DFT is the most practical and most widely used *ab initio* method. On computing resources, DFT simulations with molecular and mineral surface models of several hundred atoms can be performed routinely, depending on a number of factors including the nature of the electronic system and the size and nature of the basis set (e.g., Gaussian functions, plane waves, and numerical atomic orbitals) employed to represent the electronic wave functions. However, the system sizes typically involved in SOM research are far beyond what any quantum mechanical approach can handle. As a result, suitable model systems have to be designed. These models can include small molecules or fragments of large molecules interacting with small surface areas of minerals. Quantum mechanical approaches also permit one to simulate spectroscopic observables like nuclear magnetic resonance (NMR), ultraviolet/visible, and X-ray absorption spectroscopy (XAS). Semiempirical methods, because of the lower numerical complexity compared with fully *ab initio* methods, are capable of handling much larger system sizes, but this crucially hinges on the availability of suitable and accurate parameter sets. Of the semiempirical Hamiltonian methods, the DFTB method^[26] has emerged as a very promising approach especially for composite organic–inorganic systems such as SOM interacting with mineral surfaces. The DFTB method can simulate systems of thousands of atoms, and there is active research to push these methods to even larger systems comparable to the ones that can be handled by classical force field approaches.

The software packages available to perform *ab initio* quantum chemistry simulations include Northwest Chem (NWChem),^[27] Gaussian,^[28] General Atomic and Molecular Electronic Structure System,^[29] CP2K,^[30] Quantum Espresso,^[31] Vienna Ab initio Simulation Package,^[32] and many others (e.g., see http://en.wikipedia.org/wiki/List_of_quantum_chemistry_and_solid-state_physics_software).

Mixed Quantum Mechanics/Molecular Mechanics (QM/MM) Methods

As described earlier, classical molecular mechanics approaches can model large molecular assemblies such as

biopolymers found in SOM. However, the intermolecular interactions are limited to electrostatic and van der Waals interactions (i.e., no chemical reactions or charge transfer). On the other hand, quantum mechanical methods can address charge transfer and chemical reactions including chemisorption of soil organic molecules to mineral surfaces and other complex interactions. However, the system sizes are limited to small molecules, small representative surfaces, and small fragments of biopolymers. Thus, there have been efforts (in areas other than SOM science) to combine elements of both classical molecular mechanics and quantum chemistry to address large-scale molecular assemblies that require electronic detail. This has resulted in hybrid approaches or QM/MM methods, where one defines a relatively small embedded region of atoms to be performed with more accurate quantum chemistry methods and the large region of atoms encompassing the QM region to be performed with less computationally demanding classical mechanics. These approaches are considered to be first steps in multiscale approaches to bridge spatial and temporal scales from the electronic scale to the macroscopic scale. QM/MM has been extensively utilized in biological problems to study catalytically active sites of protein molecules and in chemistry to study the catalytically active sites of zeolite materials. Such QM/MM methods have rarely been used to study SOM. The challenge for soil science is to have an extensive QM/MM infrastructure that can handle the definition of QM and MM regions, including the possibility of having multiple QM regions to describe more than one potential chemically active interaction for a given SOM system.

Most quantum mechanical software packages mentioned earlier support QM/MM approaches. For a complete review, see, e.g., Lin and Truhlar.^[33]

BRIEF SURVEY OF MOLECULAR MODELING APPLICATIONS TO SOM

Each of the theoretical approaches described above has strengths and limitations, which shape the type of molecular models that can be designed and tackled for a given methodology. Classical molecular dynamics can address models with millions of atoms, the most of the methods described above; however, classical molecular dynamics typically cannot deal with chemical reactions and charge transfer, which involve electronic degrees of freedom that quantum chemistry methods can address. At the other end of the spectrum, quantum mechanical methods can address chemical reactions and charge transfer, but these methods can only handle several hundreds of atoms for the *ab initio* methods and thousands of atoms for the semiempirical Hamiltonian methods. Both methods have been used in the literature to address various aspects of SOM research. The exact structure of SOM is a matter of debate, and the molecular simulation research that has been done and is ongoing

can be divided into two modeling approaches according to the model of SOM adopted. The first modeling approach relies on humic acid atomistic models, notably those of Schulten^[34] and similar models for the molecular model of SOM and dissolved organic matter. The models developed by Schulten are flexible macromolecules of covalently bonded organic groups representing an average structure of SOM based on pyrolysis mass spectrometry data and molecular mechanics sampling of conformations along with quantitative–structure–activity relationship analysis (mass, surface area, volume, partial charges, polarizability, refractivity, hydrophobicity, and hydration energy statistical correlation). These models are able to demonstrate general aspects of SOM such as water and cationic bridging and hydrogen bonding between carboxylic/carboxylate functional groups and other polar and ionic functional groups and organization of complex aggregate structures. The SOM models due to the second modeling approach are derived from biomolecules and/or biopolymers. The premise here is that SOM is not structurally dissimilar from the biomolecular input (i.e., plant, microbial, and animal matter at various stages of decomposition). This model has gained support from NMR^[35] and XAS^[36] experiments.

The computational simulations adopting the Schulten humic acid model or similar models to represent SOM include the work of Sutton and Sposito,^[37] Kirkpatrick et al.,^[38] and Aquino et al.^[39] who used the Schulten humic acid molecular model (with modifications made by Sutton et al.^[40]) to study the interaction of SOM with the Ca²⁺-montmorillonite-layered clay mineral. Kirkpatrick and coworkers^[38,41,42] have used classical molecular dynamics to probe the interaction of a soil organic molecular model smaller than the Schulten humic acid model having similar properties with Ca²⁺ cations^[38,41] and Na⁺-hectorite.^[42] Aquino et al.^[39,43] have used both classical and quantum chemistry methods (DFT and DFTB) to model the interaction of carboxylate-bearing alkyl groups with water^[39] and various cations.^[43] A detailed account of these SOM modeling efforts can be found in the review by Schaumann and Thiele-Bruhn.^[44]

Simulation efforts based on the biomolecule/biopolymer approach are relatively sparse and aimed primarily at the indirect prebiotic topic. However, their insights are applicable in the soil realm as their studies involve interactions of biomolecules/biopolymers with clay mineral surfaces and cationic species. Large-scale classical molecular dynamics studies include the series of DNA–MgAl layered double hydroxide (LDH),^[13] RNA–clay (montmorillonite) surface,^[16] RNA–MgAl LDH,^[15] and ribozyme–clay (montmorillonite) surface^[14] simulations performed by Coveney and coworkers to probe how clay and LDH surfaces and intercalated spaces may be involved in the origin of life. In each of these simulations, Coveney and coworkers monitored the conformational changes of these biopolymers with respect to the clay surface to gauge whether mineral surfaces can enhance folding and mineral

Fig. 1 Rendering of model protein (Gb1 subunit) adsorbed to kaolinite proton-covered (001) basal plane from a classical molecular dynamics simulation.^[17] Left: Simulation snapshot with water molecules shown. Right: Magnified inset showing simulation snapshot with the field of water molecules surrounding the protein and adsorbed to the clay surface removed for clarity. The β -sheet (arrows) and large α -helix (coil) are slightly strained compared to the solution-phase protein with the formation of a mini α -helix at one of the β -sheet turns.

binding outcomes favorable to life. In the intercalated DNA–MgAl LDH case, Coveney and coworkers noted that, at elevated temperatures and pressures (relevant to the origins of life), the intercalation of DNA in the layered mineral enhanced the stability of DNA.^[13]

To address the subject of SOM stability in soil systems, Andersen et al.^[17–19] have embarked on a series of protein–mineral interaction molecular dynamics simulations to explore the potential stabilizing or destabilizing mechanisms of proteinaceous organic matter and the ramifications this may have on soil enzyme activity. A representative picture of one of these large-scale simulations is shown in Fig. 1. Using relatively small biomolecules, hydrophilic glucose and amphiphilic stearic acid, Petridis et al. have demonstrated complex hydrophilic and amphiphilic films on an alumina surface, which suggests the potential for physical protection of certain domains of SOM over mineral surfaces.^[45]

Because of system size limitations mentioned earlier, quantum chemistry application to the study of soil biomolecules and biopolymers has been limited to the interaction of small DNA nucleotides, amino acids, and peptides on small clay cluster or surface models and is used to study chemisorption and chemical reactions of these small molecules on these surfaces.^[46–51]

CHALLENGES AND OUTLOOK

The primary challenge of applying the described methods is the computational limitations on the number of atoms that can be simulated for complex systems such as SOM and the timescales over which the simulations can be performed. As computers become faster and algorithms become more efficient, larger and larger molecular systems will be

feasible for a given method. One burgeoning challenge with the increases in the size of molecular systems that can be simulated is the need for big data solutions to handle massive amounts of simulation data efficiently and for model-building and analysis tools to handle these data. For the simulation methods described here, improvements in performance of algorithms and strategies such as the division of computational work over multiple computer processors, including fast coprocessors such as graphical processing unit and Intel Phi, are in constant research and development.

ACKNOWLEDGMENTS

Soil Organic Matter (SOM): Nutrient Dynamics

Charles W. Rice

Department of Agronomy, Kansas State University, Manhattan, Kansas, U.S.A.

Abstract

Agriculture in the 1800s and early 1900s relied upon plowing the soil, with low crop yields; crop residues were often removed. This combination of agricultural practices resulted in reducing the replenishment of organic carbon (C) to the soil. Managing agricultural soils for sequestering C will result in additional benefits. Management practices that increase soil C also tend to reduce soil erosion, reduce energy inputs, and improve soil resources.

INTRODUCTION

Soil organic matter (SOM) is a fundamental component of soil and the global carbon (C) cycle. SOM controls many of the chemical, physical, and biological properties of the soil.^[1] The estimated amount of organic C stored in world soils is about 1100–1600 Pg, more than twice the C in living vegetation (560 Pg) or in the atmosphere (750 Pg).^[2] Hence, even relatively small changes in soil C storage per unit area could have a significant impact on the global C balance. SOM is derived mostly from plant residues. Plants convert carbon dioxide (CO₂) into tissue through photosynthesis. Upon their death, plant tissues decompose, primarily by soil microorganisms, and most of the C in the plant material is eventually released back into the atmosphere as CO₂. Between 10% and 20% of the C in plant residue forms SOM, sometimes referred to as “humus.” Some of this C can persist in soils for hundreds and even thousands of years. Associated with the C in SOM are many essential plant nutrients—primarily nitrogen (N), phosphorus (P), and sulfur (S). Concentrations of SOM range from 0.2% to over 80% in peat soils although the typical range for temperate soils is 0.4–10%.^[3] While it is a minor component of most soils, SOM is essential to the living component of soil. SOM provides the energy source for most soil microorganisms and provides the nutrient for plants and the soil biological community. Thus, knowledge of SOM dynamics is crucial for the understanding of global C cycling and plant production.

The accumulation of SOM is dependent on the quantity and quality of organic residue inputs, largely as plant material, the rates of microbial decomposition, and the capacity of the soil to store organic matter. The quality of the plant residue affects both the extent and rate of decomposition. Labile C compounds such as simple sugars degrade relatively rapidly and more completely to CO₂. On the other

end of the spectrum, lignin is more difficult to degrade. Most microorganisms do not have the capacity to completely degrade lignin to CO₂. Thus, many of the partial degradation products form the precursors to SOM. Generally, the C/N ratio is a guide of decomposability. A ratio > 30 slows decomposition and immobilizes N; a ratio < 20 releases N and allows microbial decomposition to proceed. Lignin content or lignin/N ratios are also used to assess organic matter degradability.

The rate of microbial decomposition of plant material and SOM is also a function of climate. As temperature increases, microbial activity increases; generally for every 10°C increase, microbial activity doubles ($Q_{10} = 2$). Soil water content is also important, optimum microbial activity occurs at near “field capacity” which is equivalent to 60% water-filled pore space.^[4] As soil becomes waterlogged, decomposition slows and becomes less complete. Peat soils are often a result of these waterlogged conditions. As soils dry, decomposition is also slowed. The third factor affecting the amount of SOM is soil texture—primarily clay content and mineralogy. Clay content stabilizes SOM by two mechanisms. First, organic molecules are chemically bound to clay surfaces, which retards degradation. Clays with high adsorption capacities, such as montmorillonite clays, are effective in retention of organic molecules. Second, soils with greater clay content increase the potential for aggregate formation. Macroaggregates physically protect organic matter trapped inside the aggregates from microbial degradation. Generally, aggregates > 250 µm provide the greatest protection.^[5,6]

COMPOSITION

SOM is not one definable entity. Since SOM is formed from plant material and microbial decomposition products, it is a myriad of organic compounds. There have been

Fig. 1 Schematic of plant decomposition through microbial biomass in the formation of SOM.

Source: Adapted from Paul & Clark.^[7]

several theories on the formation of soil humus, but the most widely accepted theory is that organic residues undergo decomposition by microorganisms.^[7] The altered compounds and new compounds synthesized by soil microbes polymerize through chemical or enzymatic reactions. Thus, SOM is undergoing constant transformation. Typically, most soil organic models define three pools of SOM (Fig. 1). The active pool, which is comprised of microbial biomass and labile organic compounds, makes up less than 5% of the soil organic C. The slow pool usually makes up 20–40% of the total organic C, and the recalcitrant pool makes up 60–70% of the soil C. These fractions are often defined kinetically based on laboratory mineralization.^[5,8] Microbial biomass is the processor, and the slow pool is the one in which much of the plant-associated nutrients reside for mineralization. The recalcitrant pool is material that is difficult to degrade and contains what in the older literature was known as humic and fulvic acids—fractions obtained by chemical fractionation procedures. The active pool has turnover times on the order of months to years, the slow pool takes decades to turn over, while C in the recalcitrant pool takes from hundreds to thousands of years to turn over completely. However, 2–5% of the recalcitrant pool is degraded annually. Since the recalcitrant pool is generally in equilibrium in natural systems, then the rate for formation equals the rate of degradation.

NUTRIENTS

Along with C, SOM contains important plant nutrients. SOM can be a source or sink of plant nutrients. Plant productivity is directly associated with SOM content and turnover. Approximately 90–95% of the soil N, 40% of the soil P, and 90% of the soil S are associated with SOM.^[3] Generally, the C/N/P/S ratio is 100:10:1:1. In agricultural soils, approximately 2–4% of the organic matter is rendered available for plant uptake on an annual basis. As discussed earlier, the more active pools of SOM are likely to be the major source of plant nutrients.

Nitrogen

The plant nutrient that is needed from soil in the greatest quantities is N. Approximately 90–95% of the soil N is in the organic form. The net release of organic N as inorganic N from the soil can be a significant source of N to satisfy plant needs. This process is called net N mineralization, which is the sum of two simultaneous processes, namely N mineralization and N immobilization. N mineralization, or more correctly called “ammonification,” is the conversion of organic N to ammonium (NH_4^+). N immobilization is the conversion of NH_4^+ to organic N. Microorganisms control both these processes, thus, factors that regulate microbial activity, as described earlier, will impact N availability.^[9] In addition to environmental factors, the quality of the organic substrate for microorganisms is important. Low-quality substrate, i.e., high C/N ratio, microorganisms degrading the residue require additional nutrients, primarily N. As a result, soil microorganisms assimilate or immobilize inorganic N. Plants may become deficient in N as the microbes fulfill their N need during decomposition of high C/N residue. Later as the organic material is processed, the N previously assimilated by microorganisms is re-released as inorganic N and can become available to plants. Often the release of organic N to the inorganic forms is in synchrony with plant uptake since favorable temperatures and water availability that promote microbial activity also promote plant growth.^[9,10] In the most native ecosystems and organic agriculture, N mineralization is the major source of plant N needs. In cropland, as much as 11–300 kg N ha⁻¹ can be supplied from organic matter.^[11] Further biological transformations of N occur in the soil, including nitrification (the oxidation of NH_4^+ to NO_3^-) and denitrification (conversion of NO_3^- to N_2); however, these are not directly linked to SOM and will not be discussed in this section. Please refer to Sylvia et al.^[12] for further discussion.

Phosphorus and Sulfur

S follows similar transformations as N. P is more controlled by soil chemistry and chemical transformations. Thus, SOM is not usually a major source of P by plants, except in very high organic soils. However, organic P can represent 80% of the total P in some soils. Significant amounts of P and S are contained within the microbial biomass. As a rule, a C/S or C/P ratio greater than 60 promotes the immobilization of S and P into the microorganisms.

Because of the importance of SOM to the quality of the soil and plant productivity, an understanding of SOM dynamics is critical to preserve natural ecosystems and ensure the long-term productivity of managed ecosystems. Gains and losses of SOM have added significance because it is a reservoir for global C and the associated interaction with climate change.

MANAGEMENT OF SOM TO ENHANCE SOIL QUALITY

Agriculture in the 1800s and early 1900s relied upon the plowing the soil with low crop yields, and crop residues were often removed. This combination of agricultural practices resulted in reducing the replenishment of organic C to the soil. Approximately, 50% of the SOM has been lost from soil over a period of 50–100 years of cultivation. Higher yields, return of crop residues, and development of conservation tillage practices have increased SOM. Table 1 lists several practices affecting the soil’s ability to sequester C.^[13] Examples of rates of soil C increases are summarized in Table 2.^[14] N management that increases crop productivity results in an increase in SOM.^[15] N fertilizer applied at recommended rates for 10 years increase soil C approximately 2 MTC ha⁻¹. Grassland systems can also contribute to C sequestration when properly managed. Under elevated atmospheric CO₂, the soil contained 6% more C to a depth of 15 cm compared with ambient conditions.^[16] The increase in soil C was due to increased plant production followed by incorporation into the soil. The amount of C sequestered over the 8-year experimental period was equivalent to 4 Mg ha⁻¹. Proper fire management may also increase soil C.^[17]

Managing agricultural soils for sequestering C will result in additional benefits. Increasing soil organic C include increased crop productivity and enhanced soil, water, and air quality (Fig. 2). In addition, management

Fig. 2 Relationship between SOM and soil, water, and air quality.

Source: Adapted from Lal, Follett, et al.^[14]

practices that increase soil C also tend to reduce soil erosion, reduce energy inputs, and improve soil resources.

Abstract

A limited understanding of the molecular composition of soil organic matter (SOM) inhibits the ability to routinely decipher chemical processes within soil and accurately predict how terrestrial carbon (C) fluxes will respond to changing climatic conditions and land use. To elucidate the molecular-level structure of SOM, organic matter should be extracted from the soil matrix and analyzed using high resolution mass spectrometry (HR MS). Here, we report the use of advanced solvent-based methods and sub-critical fluid extraction protocols for molecular characterization of SOM by HR MS. Combining liquid solvent extraction with super-critical fluid extraction protocols is recommended for extracting a representative fraction of SOM, especially when analysis coverage, recovery, and sensitivity are required. These approaches provide the chemical and structural detail needed to develop mechanistic descriptions of soil C flow processes.

INTRODUCTION

The focus on ecosystem stress and climate change is currently relevant as researchers and policy makers strive to understand the feedbacks between soil carbon (C) dynamics and climate change. Successful development of soil molecular profiles that link microbiology with organic C will have a great impact on assessments of soil ecosystems and vulnerability in response to climate change. Current biogeochemical models predict widely varying C uptake by the terrestrial ecosystem under future climate conditions due to insufficient understanding and representation of soil C processes and dynamics.^[1] Molecular characterization of soil organic matter (SOM) is therefore a necessary first step to develop a more complete understanding of soil C processes and dynamics, their resulting feedbacks to climate change, and a reduction in the uncertainty of predictions of future climate scenarios modeled at the regional and global scales.^[2]

The ability to address fundamental issues associated with biogeochemical cycling of C is limited because the molecular complexity of SOM compounds has prevented routine identification for wide variety of soil types and ecosystems. Early studies of SOM mostly consisted of bulk analysis (i.e., the total weight of soil fractions or elements).^[3] Structural investigations of macromolecular SOM are based on non-destructive spectroscopic techniques, such as nuclear magnetic resonance (NMR) and Fourier transform infrared (FTIR), which provide semi-quantitative analysis of the presence and identity functional groups and types of C bonds (aromatic C, alkyl C, O-alkyl C, etc.). Identification of the molecular composition of SOM typically involves the fragmentation of SOM molecules into smaller units through chemical or thermolytical degradation, which complicates reconstruction of the intact suite of individual molecules present in soils. While gas chromatography mass spectrometry (MS) provides molecular-level information of SOM compounds, only a limited number of compound classes

(i.e., aliphatic and cyclic lipids, low molecular weight phenols, and carbohydrates) are routinely identified using this approach.^[3–5]

Ultra-high resolution mass spectrometry (UHR MS) by Fourier transform ion cyclotron resonance (FTICR) MS coupled with electrospray ionization (ESI) can provide elemental composition of dissolved organic matter (DOM) molecules with ultrahigh-mass resolution and sub-ppm mass accuracy.^[6–11] ESI is based on analyte availability in solution^[12] and uses electrical energy to assist the transfer of ions from solution into the gaseous phase before they are subjected to mass spectrometric analysis, and, therefore, that is why this technique has predominantly been utilized for DOM.^[8,10] For SOM characterization, organic molecules must first be extracted from soil, preferably with little or no chemical alteration. Traditional extraction methods using strong acids and alkaline solutions have been tested on different soils; however, the resulting extracts did not generate well-defined organic matter fractions and potentially distort the SOM through chemical modification.^[13] Moreover, different organic solvents have also been utilized for extracting explosive residues in soil but not for characterization of organic matter composition.^[14] Collectively, none of these studies provided enough information of the different types of compounds extracted by each solvent, as no HR MS instrument was utilized.

Here, we present the developments of novel liquid solvent and sub- and super-critical fluid extraction (SCFE) protocols for a more representative characterization of C compounds in SOM, thereby providing the chemical and structural details needed to develop mechanistic descriptions of soil C flow processes.

Liquid solvent extraction

Liquid solvent extractions (LSEs) with methanol (MeOH), water (H₂O), acetonitrile (ACN), pyridine, chloroform, and hexane were used to extract SOM from different soil types, and then analyzed by 12 Tesla (T) FTICR MS for characterization of SOM molecular composition.^[2] Our experiments have allowed us to identify thousands of individual compounds in complex soil mixtures with a wide range of C content representing diverse ecosystems within the United States. This UHR technique generated large databases of chemical formulas for individual samples, which could be searched for specific compounds and compound classes or integrated across the entire data set to summarize the molecular characteristics of SOM (e.g., aromaticity, elemental ratios, and degree of unsaturation). The yield of the chemical extraction was dependent on: 1) the type of solvent used and its polarity; 2) sample-to-solvent ratios; and 3) the chemical and physical nature of the samples including their origins.

Extraction of specific organic molecular classes can be established by using solvents that differ in polarity. For example, hexane and chloroform are non-polar solvents that extract non-polar aliphatic compounds, such as lipids and

other compounds with high hydrogen (H) to C ratios, while MeOH, a more polar solvent, extracts compounds with intermediate oxygen (O) to C and H to C ratios. ACN, the most polar among the organic solvents tested, extracts compounds with higher O content (e.g., polyphenolic tannin-like compounds). H₂O is selective for compounds with high O to C ratios including carbohydrates and sugars in addition to the hydrophilic aromatic compounds. In testing SOM, our findings suggest that combining the ESI FTICR MS data from the four solvent (hexane, MeOH, H₂O, and ACN) extracts, each conducted on a separate soil sample, resulted in a richer representation of the diversity of organic compounds present in soil than the use of any solvent singly. As a result, we calculated a composite composition by combining the common compounds that were observed in spectra produced by three of the four solvents (MeOH, H₂O, and ACN) and the compounds that were uniquely extracted by each of the other solvents (Fig. 1). In addition, the composite composition was shown to be successful in capturing differences in composition between different soil types.^[2] These observations suggest that SOM from different ecosystems is compositionally different and that a collection of extractions are better able to capturing such differences, in spite of the variability in the classes of compounds each solvent extracts.

To minimize extraction time and sample volume, we built on the results of single solvent extraction techniques to develop sequential extraction protocols and procedures that differed by the solvent type (and hence solvent polarity) and the order of extraction. Sequential extraction methods take

Fig. 1 The CO₂-SCFE and other liquid solvent selectivity for extraction of SOM in specific ranges of O to C and H to C ratios. Composite refers to the sum of the uniquely extracted and common compounds and gives the full representation of compound diversity of organic matter in each soil. SRFA corresponds to Suwannee river fulvic acid standard purchased from International Humic Substances Society.

advantage of the fact that different SOM compounds show dissimilar reactivity toward different solutions. A single soil sample is extracted with a series of extractants, in our case, different polar and non-polar solvents, each chosen to selectively dissolve a single class or group of compounds with similar chemical characteristics. The best coverage, recovery, and selectivity was observed when the sequence was designed so that the most polar compounds are removed first by H₂O, followed by MeOH, and finally, chloroform, a non-polar solvent. The recovery from the single sample sequential extraction protocol utilizing three solvents and 100 mg of soil was comparable to the multiple sample single solvent extraction protocol utilizing six solvents and 600 mg of soil. By utilizing sequential extraction protocol, we decreased the number of solvents used and the time need to analyze the samples by half as well as decreased the amount of starting material required to generate a comparable number of extracted compounds. Both of these extraction techniques expand our depth of knowledge of molecular soil composition leading to a greater understanding to soil ecology and organic C flow.

Sub- and Super-critical Fluid Extraction

Sub- and super-critical fluid (SCFs), such as carbon dioxide (CO₂), is an extraction technique that is complementary to LSE. It has a 10–100-fold faster molecular diffusion rate than liquid solvents without surface tension.^[15] The high diffusion rate of SCFs enables high coverage of SOM by penetrating into and extracting organic molecular species out of porous soil matrices. Additionally, SCF CO₂ is chemically stable and can be removed from the sample simply by relieving the pressure without leaving behind residues in the final extraction products. This extraction technique provides concentrated intact products with high extraction recovery and sensitivity. Altering SCF operation pressure and/or temperature and modifying SCF composition with addition of polar solvents,^[15,16] such as MeOH, can easily modulate the SCFE selectivity, which has a potential to perform sequential SCFE, similar to what was described above for LSE. SCFE was initially widely explored in the 1990s^[15,16] and has recently undergone a revival and is a technique that allows broad characterization of complex organic compounds from solid matrices.

We developed an automated on-line SCFE-micro solid phase extraction (microSPE)—nanoscale liquid chromatography (nanoLC) system coupling to FT ICR MS using a nanoscale ESI interface for SOM analysis. For successful online extraction and characterization of SOM, several challenges must be addressed. The first is the purity of the SCF applied as the extraction solvent. Even high purity SCF, such as SFE-grade CO₂, contains contaminants that can be enriched by online microSPE resulting in high MS background and interfering with accurate MS to assign compounds. A graphitic C LC column can be used to purify SFE-grade CO₂ and the resultant background. Secondly,

microSPE needs to be implemented carefully to provide a sufficient sample capacity without degradation of subsequent LC separation. Implementation of nanoscale LC is favorable for highly sensitive characterization of soils while only consuming of a few milligrams of soil sample.

A tremendous amount of different molecular species (e.g., >24,000) based on their unique masses can be detected by Fourier transform MS even with the use of neat SCF–CO₂ for extraction of SOM from a small size of soil sample (e.g., 8 mg of peat). With use of high mass accuracy (i.e., with ≤1 ppm mass errors) provided by 12T FTICR MS, 7618 molecular formulas can be assigned from a single step, 3 hr, automated experiment. The great power of SCFE for extraction of SOM has been investigated to extract soil residue after been sequentially extracted by H₂O and MeOH. SCFE was able to recover additional compounds not extracted by H₂O and MeOH. The overlap between CO₂–SCFE and H₂O and MeOH extraction is less than 30%, revealing their different selectivity for SOM.

SCFE is a sensitive approach that enables extracting SOM from a small size of a soil sample. We have used a 50 µL sample vessel for SCFE with sample loading capability of 1–35 mg (the soil sample weight loaded depends on the density of soil). For low C content soils, 1 mg sample generates ~800 assigned molecular formulas, whereas 20–35 mg generates ~2600 molecular formulas.

CO₂–SCFE selectivity is similar to hexane and chloroform for extraction of SOM (Fig. 1) and provides rich information for lipids, unsaturated hydrocarbons, and protein compounds. Extraction of SOM cellulose, tannins, and amino sugars by using SCFE requires modifying CO₂ with polar solvents. Modifications that use H₂O and/or MeOH are the optimal, as it extends the SCFE capability to extract more polar molecular species in soil.

CONCLUSION

Coupling the properties of different solvents with FTICR MS enabled a wide range of compound classes to be extracted in complex soil mixtures with a wide range of C content representing diverse ecosystems within the United States. LSE and SCF extraction followed by FTICR MS is a promising tool to understand the dynamics of SOM and provides data for more accurate climate models, and the fate and transportation of C. In-depth characterization of soil biogeochemistry is an essential first step for understanding soil C processes and dynamics, including its possible feedbacks to climate change and impacts on existing biogeochemical models. We described the differences observed in the SOM composition derived from FTICR MS when different organic and aqueous solvents were used for extraction and highlighted a new approach for more representative characterization of the diversity of SOM.

Our exploration for extraction of SOM shows that the SCFE technique is an important member of a family of

extraction methods for characterization of SOM. SCFE can be performed in parallel with conventional extraction methods or used as a complementary tool for recovery of the residues remaining after LSE to enrich content and decrease biases of data sets for SOM study. The results from these experiments show that solvent extraction followed by UHR MS is a promising tool to understand the dynamics of SOM.

Soil Organic Matter (SOM): Structure and Characterization

Georg Guggenberger

Institute of Soil Science and Soil Geography, University of Bayreuth, Bayreuth, Germany

Abstract

Soil organic matter (SOM) encompasses all biologically derived organic material found in the soil or on its surface irrespective of: 1) source; 2) whether it is living or dead; or 3) stage of decomposition but excluding the aboveground portion of living plants. This implies large structural heterogeneity and close linkage to SOM functions. Litter composition and its changes during biotic and abiotic transformation are key variables in the processes and the size of carbon (C) sequestration in soil. In the context of the Kyoto Protocol, analysis of SOM structure helps us to understand these processes and to predict changes in the sign and magnitude of terrestrial C fluxes in a changing environment. To reduce SOM heterogeneity, different components of SOM need to be separated into entities that differ in terms of source, composition, and turnover. Evidence suggests that the classical chemical fractionation into fulvic acids, humic acids, and humin, according to solubility characteristics in dilute acid and base, is not useful in this respect. Fractionations that are more promising rely mostly on physical fractionations according to particle size or density and the analysis of dissolved organic matter in the soil solution.

ANALYTICAL METHODS

The analytical approaches can be divided into degradative methods involving chemolysis, thermolysis, or thermochemolysis and non-invasive spectroscopic techniques such as nuclear magnetic resonance (NMR) spectroscopy (Table 1).^[1–6] Degradative methods provide molecular-level information on specific organic compounds accessible to the degradative step, whereas spectroscopic techniques inform on the bulk composition of soil organic matter (SOM). Since all analytical approaches have their drawbacks, a comprehensive picture of the SOM structure can only be obtained using a combination of various methods.^[7]

Degradative Methods

Chemolysis of SOM involves various degradation procedures (hydrolysis, oxidation, and extraction) that are selective in their attack on specific molecular structures (Table 1). The techniques are well suited to follow the often subtle changes in the composition of plant- and microbial-derived biopolymers during microbial transformation processes, in particular when different soil fractions are comparatively investigated.^[9,36] But only a part of SOM present in specific structures—as determined by NMR spectroscopy—can be identified with these techniques, and information on the original macromolecular structure of SOM is limited.^[37]

Analytical pyrolysis uses thermal degradation to cleave bonds in the organic macromolecules and enables a sensitive and rapid characterization of organic constituents.^[23]

Problems may arise due to the complicated pyrolysis behavior of many organic compounds, in particular in the presence of catalytic minerals. Thermal secondary reaction causes considerable modification of the organic compound, which may bias the interpretation of the pyrolysis products with respect to their mother compounds.^[24,25] Some of the problems can be solved by thermochemolysis utilizing tetramethylammonium hydroxide.^[25,38] Hydroxyl and carboxyl groups are converted into their respective methyl ethers and methyl esters to avoid fragmentation of aliphatic and benzenecarboxylic acids.

Spectroscopic Techniques

NMR spectroscopy has a large potential to analyze the different chemical species of ^1H , ^{13}C , ^{15}N , and ^{31}P nuclei in solution and solid (not ^1H) state. With the cross-polarization magic angle spinning pulse sequence, the chemical structure of C and nitrogen (N) can be characterized *in situ* non-destructively, and within a feasible time of analysis.^[28,29] However, even with completion of detailed experiments on rates of signal generation and relaxation for each type of carbon (C),^[30] quantitative analysis of NMR data is not possible in the presence of paramagnetic species. Samples containing charred materials cannot be quantified by the CP technique; instead, the C nuclei must be directly excited using a Bloch decay sequence.^[33] Additional information on the structure of soil organic C can be obtained by specific pulse sequences such as interrupted decoupling (ID), proton spin relaxation editing, and mixing of proton spins (for literature see Baldock and Nelson^[1]). Of the other spectroscopic techniques, infrared spectroscopy provides

Table 1 Important degradative and non-degradative techniques to study SOM structure.

Technique	Components addressed	Applications	Drawbacks	References
Chemolytic techniques	Address defined biomolecules released mostly as their monomer units from the organic matrix by an appropriate chemical treatment	Analysis of defined organic components of plant, microbial and pyrogenic origin often well-suited as biomarkers	Only about 60% (fresh organic residues) to about 20% (transformed, mineral-associated compounds) of SOM is characterized	[7,8]
Acid hydrolysis	Polysaccharides	Distinguishes different types of polysaccharides by sequential extraction Pattern of monosaccharides released gives information on the source (plant vs. microorganisms)	Not all polysaccharides are hydrolyzable Yield differs for different types of with organic matter	[9,10]
	Proteinaceous compounds	Comprises the dominant form of organic nitrogen in soil Assessment of D/L ratios	Only a part of the proteinaceous compounds is hydrolyzable	[11,12]
	Amino sugars	Traces microbial input to SOM Distinguishes between fungal and bacterial residues	Source of some amino sugars is not well defined	[13,14]
Solvent extraction	Extractable lipids	Comprises hydrophobic aliphatic compounds of various origins	Complex and polymerized lipids are only scarcely accessible	[15,16]
Saponification	Cutin and suberin components	Detects aliphatic biopolymers derived from vascular plants	Does not comprise non-ester plant biomacromolecules	[17]
CuO oxidation	Lignin	Traces plant input to SOM Informs about type of plant Informs about lignin decomposition in soil	Only cleaves arylether bondings Yield is not defined and decreases with increasing lignin decomposition	[18,19]
	Cutin and suberin components	Detects aliphatic biopolymers derived from vascular plants	Does not comprise non-ester plant biomacromolecules	[20]
HNO ₃ oxidation	Pyrogenic C	Traces the highly aromatic core of charred organic components	Yield varies with the type of the charred organic components	[21,22]
Analytical pyrolysis	Products of SOM released by thermal degradation	Pattern of pyrolysis products allows detailed information on the chemical composition of the parent molecules Well suited for biomarker analysis	Volatilization of different types of pyrolysis fragments varies Pyrolysis fragments may have different sources Secondary pyrolysis reactions may occur	[23,24]
Py-GC MS	Pyrolysis products that are volatile to be separated by gas chromatography	Separates pyrolysis products that have the same mass/charge (m/z) ratio	Non-volatile pyrolysis products cannot be detected	[25]
Py-FIMS	Pyrolysis products are treated by soft ionization technique	Soft ionization produces predominantly molecular ions of the pyrolysis products	Volatilization decreases with increasing polarity of the fragments	[23]
Thermochemolysis with TMAH	In particular aliphatic and benzenecarboxylic acids as their methyl esters	Pyrolysis/methylation renders polar products volatile for gas chromatographic separation	Reproducibility needs to be improved	[26,27]
NMR spectroscopy	Analysis of all C, H, N, or P species within a solid or soluble sample	Signal intensity relates to the concentration of nuclei creating the signal	Most applications are not quantitative	[28,29,30,31]

(Continued)

Table 1 Important degradative and non-degradative techniques to study SOM structure. (Continued)

Technique	Components addressed	Applications	Drawbacks	References
Solution ^{13}C , ^1H , ^{15}N , and ^{31}P NMR spectroscopy	Analysis of C, H, N, and P species in aqueous samples	Composition of C, H, and N species in the soil solution and in alkaline extracts (humic and fulvic acids)	Insoluble compounds are not detected	[32]
CP MAS ^{13}C , and ^{15}N spectroscopy	Analysis of C and N species in solid samples	Characterization of the chemical structure of organic C and N <i>in situ</i> and non-destructively	Limited quantitative interpretation caused by paramagnetic species, by different C and N relaxation, by spinning side bands, and by the cross-polarization technique	[28,29]
BD ^{13}C NMR spectroscopy	Analysis of C species in solid samples	Direct excitation of ^{13}C spins enables analysis of charred materials	Very time consuming	[33]
IR spectroscopy (FTIR and DRIFT)	Analysis of C species in solid samples	Informs on the type of atoms to which C is bonded and on the nature of the bond	Reveals only a few well-resolved peaks	[34]
			Signals from minerals often dominate	[35,34]

information on the type of atoms to which C is bonded and on the nature of the bond,^[35] whereas electron spin resonance spectroscopy gives information about free radicals in SOM.^[39]

CHEMICAL STRUCTURE OF SOM

Individual Plant and Microbial Components

Individual components derived from plants (primary resources) and microorganisms (secondary resources) can be considered as the parent material of SOM. Within plant and microbial tissues, polysaccharides are generally the most important organic components. Analysis of sugar monomers released by hydrolysis or pyrolysis revealed that crystalline and non-crystalline plant polysaccharides are rapidly decomposed and microbial polysaccharides accumulate in soil.^[8,40] Most amino sugars in soil are also of microbial origin, predominantly from fungal chitin and bacterial peptidoglycan.^[13] An important biopolymer in soil is vascular plant-derived lignin with its *p*-hydroxyphenyl, guaiacyl, and syringyl monomeric units. The pattern of lignin monomers can be used to identify the primary resource of SOM; in contrast to angiosperm lignin, gymnosperm lignin does not contain syringyl units. In soil, lignin is decomposed in aerobic environments via side-chain oxidation and ring opening.^[41,42] This results in a shortening of alkyl side chains and an increase in carbonyl and carboxyl groups. Thus, parts of the lignin degradation products are water soluble^[41] and represent, together with

the polysaccharides, the majority of the dissolved organic matter in soil.^[6] The third major component is free and bound lipids of plant and microbial origin, including waxes, organic acids, steroids, glycerides, and phospholipids.^[3,17] Plant cutin and suberin (insoluble polyesters) can be easily decomposed,^[43] while non-saponifiable cutan and suberan (insoluble non-polyesters) appear to be resistant to degradation.^[44] Some aliphatic compounds of microbial origin are also selectively preserved.^[45]

The SOM Continuum

SOM is generally composed of the above-mentioned plant and microbial residues and their transformation products.^[7,46] The latter refers largely to the term “humic substances,” as frequently used in older references.^[47,48] There has been a shift in paradigm away from humic substances. Organic matter degradation is considered to be predominantly a process of attrition, during which relatively resistant biomolecules are selectively concentrated.^[49] In surface soil horizons with large inputs of plant residues, the SOM continuum varying from fresh residues to highly degraded components is dominated by the former material.^[7] In contrast, SOM in subsoil horizons is enriched by highly altered, recalcitrant organic materials that can only be characterized to a minor extent by chemolytic treatments.^[49] Accessibility of these compounds is limited to (chemo)thermolytic and spectroscopic methods.

In aging SOM, Schulten, Leinweber, and Reuter^[50] and Schulten and Leinweber^[23] observed that increasing

Fig. 1 (A) Thermograms for compound classes evolved by pyrolysis-field ionization from clay (above), fine silt (center), and medium silt (below) from a humus formation experiment after 13 and 34 years of soil development and (B) solid-state ¹³C NMR spectra of the clay fraction isolated from soils of different pedogenesis.

Source: From Kögel-Knabner^[10] and Schulten & Leinweber.^[23]

amounts of thermal energy applied in pyrolysis-field ionization mass spectrometry were required for volatilizing lignin dimers, alkylaromatics, and lipids (Fig. 1A). The authors suggested that the development of stronger chemical bonds was due to either formation of 3-D cross-linking by aryl-alkyl combinations or by formation of strong organic-mineral complexes. Kögel-Knabner^[7] concluded from ID pulse sequences at ¹³C NMR spectroscopy that cross-linked aliphatic compounds accumulate during SOM decomposition.

The pedogenic environment has a large impact on the structure of SOM. This can be particularly confined by solid-state ¹³C NMR spectroscopy of mineral-associated organic matter, while spectra obtained on bulk samples are influenced by plant residues that are rather similar in composition.^[37] The Mollisol in Fig. 1B is characterized by about similar contributions of alkyl (0–50 ppm), O-alkyl (50–110 ppm), aromatic (110–160 ppm), and carboxyl/amide (160–200 ppm) C. In contrast, Alfisols and Ultisols

show a high proportion of alkyl and O-alkyl C, and Spodosols are dominated by alkyl C.

Further work may benefit from the application of microscopic and non-destructive microspectroscopic techniques to investigate SOM within its mineral and microbiological soil environment. For in-depth information on modern methodological approaches and concepts on SOM structure, the excellent reviews of Kögel-Knabner,^[37] Baldock and Nelson,^[1] and Hedges et al.^[49] are recommended.

Davis, California, U.S.A.

Julie D. Jastrow

Environmental Research Division, Argonne National Laboratory, Argonne, Illinois, U.S.A.

Abstract

Soil organic matter (SOM) is a dynamic entity. The amount (stock) of organic matter in a given soil can increase or decrease depending on numerous factors including climate, vegetation type, nutrient availability, disturbance, land use, and management practices. But even when stocks are at equilibrium, SOM is in a continual state of flux; new inputs cycle—via the process of decomposition—into and through organic matter pools of various qualities and replace materials that are either transferred to other pools or mineralized. An understanding of SOM turnover is crucial for quantifying carbon (C) and nutrient cycles and for determining the quantitative and temporal responses of local, regional, or global C and nutrient budgets to perturbations caused by human activities or climate change.

INTRODUCTION

Soil organic matter (SOM) is a dynamic entity. The amount (stock) of organic matter in a given soil can increase or decrease depending on numerous factors including climate, vegetation type, nutrient availability, disturbance, land use, and management practices. But even when stocks are at equilibrium, SOM is in a continual state of flux; new inputs cycle—via the process of decomposition—into and through organic matter pools of various qualities and replace materials that are either transferred to other pools or mineralized. For the functioning of a soil ecosystem, this “turnover” of SOM is probably more significant than the sizes of SOM stocks.^[1] An understanding of SOM turnover is crucial for quantifying carbon (C) and nutrient cycles and for determining the quantitative and temporal responses of local, regional, or global C and nutrient budgets to perturbations caused by human activities or climate change.^[2]

DEFINITION OF SOM TURNOVER

The turnover of an element [e.g., C, nitrogen, and phosphorus] in a pool is generally determined by the balance between inputs (I) and outputs (O) of the element to and from the pool as shown in Fig. 1. Turnover is most often quantified as the element's mean residence time (MRT) or its half-life ($T_{1/2}$). The MRT of an element in a pool is defined as 1) the average time the element resides in the pool at steady state or 2) the average time required to completely renew the content of the pool at steady state. The term half-life is adopted from radioisotope work, where it is

defined as the time required for half of a population of elements to disintegrate. Thus, the half-life of SOM is the time required for half of the existing stock to decompose.

The most common model used to describe the dynamic behavior or turnover of SOM is the first-order model, which assumes constant zero-order input with constant proportional mass loss per unit time^[3,4]

$$\frac{\partial S}{\partial t} = I - kS \quad (1)$$

where S is the SOM stock, t is the time, k is the decomposition rate, and kS is equivalent to output O. Assuming equilibrium ($I = O$), the MRT can then be calculated as

$$MRT = \frac{1}{k} \quad (2)$$

and MRT and $T_{1/2}$ can be calculated interchangeably with the formula as follows:

$$MRT = T_{1/2} / \ln 2 \quad (3)$$

MEASURING SOM TURNOVER

Most often the turnover of SOM, more specifically the turnover of SOM-C, is estimated by one of four techniques:

1. Simple first-order modeling
2. ^{13}C natural abundance technique
3. ^{14}C dating technique
4. “Bomb” ^{14}C technique

Fig. 1 The turnover of SOM is determined by the balance of inputs and outputs. Total SOM consists of many different pools that are turning over at different rates. The MRT of total SOM is a function of the turnover rates of its constituent pools.

This list does not include tracer studies where a substrate (e.g., plant material) enriched in ^{13}C , ^{14}C , and/or ^{15}N is added to soil, and its fate is followed over time. Most studies of this type (see Schimel,^[5] for a review) use the tracers to quantify the short-term (1–5 years) decomposition rate of freshly added material rather than the long-term turnover of whole-soil C.

Eqs. 1 and 2 form the basis for estimates of SOM turnover derived from first-order modeling; the unknown k is calculated as

$$k = \frac{I}{S}$$

by assuming a steady state

$$\frac{\partial S}{\partial t} = 0.$$

This approach requires estimates of annual C input rates, which can be assumed to be continuous or discrete.^[3] The input can also be written as

$$I = hA$$

where A is the annual addition of C as fresh residue and h (the isohumification coefficient) represents the fraction that, after a rapid initial decomposition of A , remains as the actual annual input to S . An estimate of h is then necessary. A value of 0.3 is commonly used for agricultural crops, but the value can be higher for other materials such as grasses or peat.^[6,7]

Another approach to estimate k by first-order modeling is “chronosequence modeling.”^[8] An increase (or decrease) in C across a chronosequence of change in vegetation, land use, or management practice can be fitted to a first-order model

$$S = S_e \left[1 - \left(\frac{S_e - S_0}{S_e} \right) e^{-kt} \right]$$

which is equivalent to

$$S = S_0 + (S_e - S_0)(1 - e^{-kt}) \quad (4)$$

where t is the time since the change, S_e is the C content at equilibrium, and S_0 is the initial C content before the change ($t=0$). An average value of I can then be calculated

$$I = kS_e$$

but in this case I represents annual inputs of new SOM (hA) rather than inputs of fresh litter or detritus. This approach is also used for chronosequences of primary succession (e.g., on glacial moraines, volcanic deposits, river terraces, and dune systems), in this case $S_0=0$.^[4]

The ^{13}C natural abundance technique relies on 1) the difference in ^{13}C natural abundance between plants with different photosynthetic pathways [Calvin cycle (C_3 plants) vs. Hatch–Slack cycle (C_4 plants)] and 2) the assumption that the ^{13}C natural abundance signature of SOM is identical to the ^{13}C natural abundance signature of the plants from which it is derived.^[9] Thus, where a change in vegetation type has occurred at some known point in time, the rate of loss of the C derived from the original vegetation and the incorporation of C derived from the new vegetation can be inferred from the resulting change in the ^{13}C natural abundance signature of the soil. The turnover of C derived from the original vegetation is then calculated by using the first-order decay model

$$\text{MRT} = \frac{1}{k} = \frac{t}{\ln(S_i/S_0)} \quad (5)$$

where t is the time since conversion, S_t is the C content derived from original vegetation at time t , and S_0 is the C content at $t = 0$. For further details on the technique, see Cerri et al.^[9] and Balesdent and Mariotti.^[10]

The presence of ^{14}C with a half-life of 5570 years in plants and the transformation of this ^{14}C into SOM with little isotopic discrimination allows the SOM to be dated, providing an estimate of the age of the SOM. The ^{14}C dating technique is applicable within a time frame of 200–40,000 years; samples with an age less than 200 years are designated as modern (see Goh,^[11] for further details of the methodology).

Thermonuclear bomb tests in the 1950s and 1960s caused the atmospheric ^{14}C content to increase sharply and then to fall drastically after the tests were halted. This sequence of events created an *in situ* tracer experiment; the incorporation of bomb-produced radiocarbon into SOM after the tests stopped allows estimates of the turnover of SOM. Further details of the technique are described by Trumbore,^[2] Goh,^[12] and Harrison et al.^[13]

RANGE AND VARIATION IN ESTIMATES OF TOTAL SOM TURNOVER

The comparisons of MRT values estimated by the four methods previously described (see Table 1) reveal a wide range of MRTs. Although variations within each method are attributable to differences in vegetation, climate, soil

type, and other factors, the largest variations in observed MRTs are method dependent. For example, MRTs estimated by simple first-order modeling and ^{13}C natural abundance are generally smaller by an order of magnitude than MRTs estimated by radiocarbon dating, because of the different time scales that the two methods measure. The ^{13}C method is generally used in medium-term observations or experiments (5–50 years); hence, this method gives an estimate of turnover dominated by relatively inputs and C pools that cycle within the time frame of the experiment. In contrast, the oldest and most recalcitrant C pools dominate estimates by radiocarbon dating because of the long-term time frame (200–40,000 years) that this method measures.^[11]

FACTORS CONTROLLING SOM TURNOVER

Primary production (specifically, the rate of organic matter transfer belowground) and soil microbial activity (specifically, the rates of SOM transformation and decay) are recognized as the overall biological processes governing inputs and outputs and, hence, SOM turnover. These two processes (and the balance between them) are controlled by complex underlying biotic and abiotic interactions and feedbacks, most of which can be tied in some way to the state factor model of soil formation.^[4] Climate (especially temperature and precipitation) constrains both production and decomposition of SOM. Vegetation type affects

Table 1 Range and average MRTs of total soil organic C in various ecosystem types as estimated by four different methods.

production rates and the types and quality of organic inputs (e.g., below- vs. aboveground, amounts of structural tissue, C/N and lignin/N ratios), as well as the rates of water and nutrient uptake—all of which, in turn, influence decomposition rates. The types, populations, and activities of soil biota control decomposition and nutrient cycling/availability and hence influence vegetative productivity. Parent material affects SOM turnover as soil type, mineralogy, texture, and structure influence pH, water and nutrient supply, aeration, and the habitat for soil biota, among other factors. Topography modifies climate, vegetation type, and soil type on the landscape scale and exerts finer-scale effects on temperature, soil moisture, and texture. Lastly, time affects whether inputs and outputs are at equilibrium, and temporal scale influences the relative importance of various state factor effects on production and decomposition.

Disturbance or management practices also exert considerable influence on SOM turnover via direct effects on inputs and outputs and through indirect effects on the factors controlling these fluxes. An example of management effects on MRT is illustrated in Table 2; in most cases, the MRT of whole-soil C is significantly longer under no tillage agriculture than under conventional tillage practices.

TURNOVER OF DIFFERENT SOM POOLS

The previous discussion is focused on the turnover and MRT of whole-soil C; hence, it treats SOM as a single, homogeneous reservoir. But, in fact, SOM is a heterogeneous mixture consisting of plant, animal, and microbial materials in all stages of decay combined with a variety of decomposition products of different ages and levels of complexity. Thus, the turnover of these components varies

continuously, and any estimate of MRT for SOM as a whole merely represents an overall average value (Fig. 1).

Although average MRTs are useful for general comparisons of sites or the effects of different management practices, they can be misleading because soils with similar average MRTs can have very different distributions of organic matter among pools with fast, slow, and intermediate turnover rates.^[2,31] Simulation models that account for variations in turnover rates for different SOM pools are used to generate more realistic descriptions of SOM dynamics. A few models represent decomposition as a continuum, with each input cohort following a pattern of increasing resistance to decay,^[32] but most models are multicompartmental, with several organic matter pools (often 3–5) that are kinetically defined with differing turnover rates. For example, the CENTURY SOM model^[33] divides soil C into active, slow, and passive pools, with MRTs of 1.5, 25, and about 1000 years, respectively, and separates plant inputs into metabolic (readily decomposable; MRT of 0.1–1 years) and structural (difficult to decompose; MRT of 1–5 years) pools as a function of lignin/N ratio. Even though compartmental models are reasonably good at simulating changes in SOM, the compartments are conceptual in nature, and thus it has been difficult to relate them to functionally meaningful pools or experimentally verifiable fractions.^[34,35]

The use of isotopic techniques to analytically determine the MRTs of physically and chemically separated SOM fractions has demonstrated the existence of various turnover rates for different pools. For example, low-density SOM (except for charcoal) invariably turns over faster than high-density, mineral-associated SOM, and hydrolyzable SOM turns over faster than non-hydrolyzable residues.^[36,37] The MRTs of primary organomineral associations generally increase with decreasing particle size, although there are exceptions (particularly among fine

gradations of silt- and clay-sized particles) that have been variously related to climate, clay mineralogy, and fractionation methodology.^[34,38,39]

For a given set of biotic and abiotic conditions, the turnover of different SOM pools depends mechanistically on the quality and biochemical recalcitrance of the organic matter and its accessibility to decomposers. With other factors equal, clay soils retain more SOM with longer MRTs than do sandy soils.^[40] Readily decomposable materials can become chemically protected from decomposition by association with clay minerals and by sorption to humic colloids.^[38,41] Clay mineralogy also plays an important role. For example, montmorillonitic clays and allophanes generally afford more protection than illites and kaolinites.^[42] In addition, the spatial location of SOM within the soil matrix determines its physical accessibility to decomposers. Relatively labile material may become physically protected by incorporation into soil aggregates^[43] or by deposition in micropores inaccessible even to bacteria. Studies of the average MRTs of organic matter in macroaggregates vs. microaggregates show consistently slower turnovers in microaggregates (Table 3). Thus, a much higher proportion of the SOM occluded in microaggregates consists of stabilized materials with relatively long MRTs.

Soluble Salts: Translocation and Accumulation

Jimmie L. Richardson

Department of Soil Science, North Dakota State University, Fargo, North Dakota, U.S.A.

Abstract

Translocation and accumulation of soluble salts in soils encompass both physical transport through a landscape to an accumulation area and soil profile processes of accumulation at that point. Soluble salts accumulate by sequences of mineral precipitation (evaporite sequences) that control the salt types of the resulting evaporite deposits either in or on the soil. These processes are driven by water that is invariably in the soil, not surface water. The water progressively becomes more concentrated in dissolved solids either by dissolving more salts as the water travels in the landscape or by losing water to the atmosphere via evapotranspiration. Either way, the dissolved solids precipitate as salts in zones in discharge areas on the landscape.

TRANSLOCATION IN LANDSCAPES

In a landscape, step one of salt translocation results from removal of labile salts in the recharge and throughflow zones of the landscape and saturated, often-transient flow, to the discharge zones. Dissolution occurs in soils located in the recharge zone of landscapes when rain-water or snowmelt infiltrates and percolates through soil or geologic materials. The landscape sources of water can be divided into local, regional, and irrigation water. Local water moves as transient flow (interflow or throughflow) from nearby areas either in periods of wetness or from local water sources. The regional systems are larger scale created by fracture or aquifer flow to the accumulation areas, often via artesian aquifers that discharge under pressure. Irrigation water is gathered from distant streams, aquifers, or other source areas and transported in engineered channel or pipe systems to the accumulation sites. Landscape translocation removes salts from recharge areas and transfers the dissolved solids to discharge areas where accumulation can occur.

Accumulation, or step two of translocation within the landscape, occurs because inefficient water removal exists during discharge. In semiarid and arid climates, the lack of water and the high potential evaporation rates create conditions with poorly integrated intermittent streams. Thus, when water is present, it cannot be transported externally from the accumulation zones or saline soils. In young or constructional landscapes, such as a Pleistocene or Holocene lake or till plain, an integrated drainage network has usually not developed; without drainage channels water cannot be effectively removed. For example, in Grand Forks County, North Dakota, the subhumid climate with 0.5 m of annual precipitation at about 45 degrees north latitude maintains relatively low evaporation potentials. Over 25% of the land area is variously impacted by saline or sodic soils. Saline soils have a saturated paste electrical

conductivity that exceeds 4 dS/m, and sodic soils have sodium (Na) absorption ratios exceeding 12 dS/m. Some areas that are strong discharge areas or receive abundant water in deserts have very high evaporation potentials and ineffective drainage. These result in hypersalinity or salinity that exceeds an electrical conductivity of 20 dS/m. The Bonneville Salt Flats, which lie around the Great Salt Lake in Utah, are examples.

Accumulation sites often have a high water table either seasonally or periodically during pluvial times of drought-pluvial cycles. At these sites, increases in salinity correlate best to pluvial or wetter periods because this is when the water table is the highest and evapotranspiration losses concentrate salts from the water table. Irrigation water creates a perpetually pluvial condition that often creates a high water table, resulting in persistent salinization. Salinization or sodification potentially occurs rapidly unless adequate drainage has been established before irrigation.

As a short synopsis of influence of the landscape, the translocation of dissolved solids relates closely to periods of saturated flow whereby salts increase as the path of transportation increases and water is lost to evapotranspiration.

TRANSLOCATION AND ACCUMULATION WITHIN SOILS

Translocation of salts within the soil involves a constant flux between the upward water losses by matric and osmotic flow and the downward infiltration and subsequent percolation of rain or irrigation water. The actual accumulation in the root zone of plants, which follows, relates to matric flow and osmotic flow. In matric flow, which is often called capillarity, water moves slowly from wet soil to dry soil. The flow direction is independent of gravity, instead it is dictated by moisture content and the matric potential

possessed by the soil. Soils with abundant surface area, such as those with clay textures, tend to have higher matric potentials at given water contents. In osmotic flow, water moves from low salt content to high salt content. Soil salinity increases hygroscopic water because of the increase in osmotic potential, often to the point where a soil looks moist but plants cannot obtain water.

Salt efflorescences often disappear after a rain event because the water that infiltrates carries the labile salts downward. Often, however, casts of less soluble minerals remain, such as gypsum, are good indicators of saline condition. The salt efflorescence will return after a few rainless days with high evaporation stress. As evaporation stress occurs on the soil, the matric forces move water to the surface where the water vaporizes and the salts precipitate. Few really labile minerals form in the soil. Usually when somebody notes a “salt” in the soil it is gypsum. One exception is the winter precipitation of mirabilite. Mirabilite is a Na sulfate that has 10 waters of hydration. With such a high amount of hydrogen bonding the ice-like crystals form easier at cool temperatures.^[1,2] The usual events that tend to dominate saline soils are evaporative and discharge driven by evaporation with flow reversals during rainfall, irrigation, or snowmelt events.

Saline seeps occur in Western United States and Canada when an aquifer is activated during a pluvial time of the pluvial–drought cycle. The aquifer does not function unless enough water reaches it to create saturated flow. Once saturated flow occurs, the water moves quickly to points of discharge on the landscape and the seepage water dries out in the air or by plant usage, leaving the salts behind. In these cases, the translocation to the soil is lateral from the

landscape. A possible rule of thumb for the recharge area of most small saline seeps is about 100 m or less.

Precipitation of translocated salts occurs in sequence as evaporation or evapotranspiration concentrates water. First to form is calcite that removes 1 mole each of calcium (Ca) and carbonate for every mole of calcite formed. Depending on which of these two ions is dominant, the next to form is either gypsum or magnesium (Mg) calcite or dolomite with a rise in pH. In fact if the pH is over 8.5, one can almost be sure that the dominant carbonate is of Na.^[3]

One mole of gypsum removes 1 mole of Ca and 1 mole of sulfate. If the sulfate is dominant over Ca as gypsum precipitates, the water and the salt efflorescence become high in Na and Mg with sulfate and chloride as the anions.^[3] Although the Eugster and Jones model was for a fully closed basin system, their sequence of evaporites is a good predictive tool in most saline situations because these situations represent groundwater discharge or ineffective drainage that act like a closed basin system or labile ion sink.

Solute Transport

Arne E. Olsen

University of Florida, Gainesville, Florida, U.S.A.

James W. Jawitz

Soil and Water Science Department, University of Florida, Gainesville, Florida, U.S.A.

Abstract

The movement of chemicals through the soil environment has been the primary focus of agricultural and environmental soil physics during the last several decades. Agricultural physicists have focused on the movement of nutrients into and through the rooting zone, with the goal of maximizing the amount of nutrient uptake while limiting the amount of nutrients passing through the root zone. Environmental soil physicists have focused on describing the movement of wastes (industrial, commercial, and residential) through the soil system. The two fields converge with respect to the movement of pesticides and excess nutrients, and these areas have proven to be fertile areas of research. Without regard to the area of study, significant advancements in the field of chemical transport through the soil system have been made in the preceding decades. The intent of this entry is to elucidate the fundamental concepts of chemical transport in the soil environment, including interactions of soil water, soil solids, and the chemicals of interests.

PRINCIPLES OF SOLUTE TRANSPORT

The movement of chemicals through the soil environment is generally described in terms of three fundamental mechanisms: advective transport, diffusive transport, and dispersive transport.^[1] These transport mechanisms are combined with the principle of continuity (or conservation of mass) to arrive at a general transport equation known as the Advection–Dispersion Equation (ADE).

For a 1-D system, the continuity equation has the form:

$$\frac{\partial M_s}{\partial t} = -\frac{\partial J_s}{\partial z} \quad (1)$$

where M_s is the total solute mass per volume of porous media [ML^{-1}], t is the time [T], J_s is the solute flux [$\text{ML}^{-1}\text{i}^{-1}$], and z is the spatial dimension [L]. Eq. 1 states that the change in solute mass storage is equal to the change in solute flux (or flux divergence). For a solute that reacts with the soil solids, the total mass of solute in the system can be expressed as:

$$M_s = \theta C_w + \rho_b S \quad (2)$$

where θ is the water content of the soil on a volume basis [L^3h^{-3}], C_w is the solvent-phase concentration [ML^{-3}], ρ_b is the bulk density of the porous media [ML^{-3}], and S is the mass of solute sorbed per unit mass of porous media [MM^{-1}]. Sorption is the interaction of a solute with a solid surface, generally described as either adsorption (interaction at the surface) or absorption (penetration of the solute into the solid).

The total solute flux is the sum of the advective and dispersive fluxes (J_A and J_D):

$$J_s = J_A + J_D \quad (3)$$

Advection

The advective flux describes the movement of solutes with the bulk solvent flow:

$$J_A = q_w C_w \quad (4)$$

where q_w is the solvent flux (or specific discharge) [LT^{-1}]. The flux of the solvent can be described using either Darcy's equation for saturated conditions or Buckingham's modification to Darcy's equation for unsaturated conditions:

$$q_w = -K(\theta) \frac{\partial h}{\partial z} \quad (5)$$

where $K(\theta)$ is unsaturated hydraulic conductivity [LT^{-1}] and h is the total hydraulic head [L].

Diffusion

Diffusion results from thermally induced agitation of solute molecules (i.e., Brownian motion). In soil solutions where concentration gradients exist, the random movement of molecules will tend to cause molecules in the higher concentration regions to move through the solvent to areas of lower concentration. This process is mathematically

modeled using Fick's First Law, which relates the solute flux density to the concentration gradient and a constant of proportionality that is dependent on the solute of interest. Fick's Law can be written for the 1-D case as:

$$J_{\text{Diff}} = -D_0 \frac{\partial C_w}{\partial z} \quad (6)$$

where D_0 is the diffusion coefficient [$L^2 t^{-1}$].^[2] For diffusion in porous media, the diffusion coefficient must be modified to account for the irregular flow network, thus the diffusion coefficient for flow in soils has been defined as:

$$D_s = D_0 \theta \Gamma \quad (7)$$

where Γ is the tortuosity, an empirical parameter that relates the straight line path to the actual roundabout path through the solvent-filled pores.^[3] In soils, solute movement resulting from molecular diffusion is generally very slow relative to advective and dispersive transport.

Dispersion

Neither pore sizes nor velocities are uniform throughout porous media, and there are a wide range of pore sizes. Advection through pores of differing sizes results in dispersion of the solute. Solute spreading resulting from this differential advection is referred to as mechanical dispersion, D_m [$L^2 T^{-1}$]. The spreading processes of mechanical dispersion and molecular diffusion are linearly combined and referred to as hydrodynamic dispersion, D [$L^2 T^{-1}$]:

$$D = D_s + D_m \quad (8)$$

Conceptually and mathematically, such spreading can be approximated by analogy to molecular diffusion. Thus, the dispersive solute flux can be written as:

$$J_D = -\theta D \frac{\partial C_w}{\partial z} \quad (9)$$

The effects of molecular diffusion are small compared to mechanical dispersion when the solvent velocity is large. As the solvent velocity approaches zero, the diffusion term dominates.

ADVECTION-DISPERSION EQUATION

Substitution of Eqs. 2, 4, and 9 into Eq. 1 yields the ADE for reactive solute transport through porous media:

$$\frac{\partial(\theta C_w + \rho_b S)}{\partial t} = -\frac{\partial q_w}{\partial z} + \frac{\partial}{\partial z} \left(\theta D \frac{\partial C_w}{\partial z} \right) \quad (10)$$

Note that this form of the ADE does not include a source-sink term.

SORPTION

Reactive solutes interact with the solid matrix during flow, as opposed to ideal or nonreactive solutes that are transported passively through the porous medium with no interactions with the solid matrix. Natural soils are composed of charged particles, and these may be clay minerals that have developed surface charge due to isomorphous substitution or organic or clay minerals that have developed charge from pH effects. When the solute and the soil system are oppositely charged, the solute is attracted to the soil surface, resulting in a retarded rate of transport through the soil. Hydrophobic interactions that promote partitioning of non-polar solutes into organic matter in soils may similarly retard solute transport.

For reversible reactions, a solute may be sorbed and desorbed by the porous medium. The solute is therefore distributed between the solvent and solid phases. In order to write the ADE in terms of solvent-phase concentration, it is necessary to develop a functional relationship between C_w and S . Various functional expressions, usually referred to as sorption isotherms, are possible. Reversible, instantaneous sorption isotherms are either linear or non-linear. For the linear case, sorbed-phase and solvent-phase solute concentrations are related by a proportionality constant called the distribution coefficient, K_d [$L^3 M^{-1}$]:

$$S = K_d C \quad (11)$$

Two alternative models are frequently used to describe non-linear sorption isotherms: Freundlich and Langmuir. Freundlich isotherms have the form:

$$S = K_d C_w^N \quad (12)$$

where N is a dimensionless empirical constant. Generally, isotherms with N is a dimensionless empirical constant. Generally, isotherms with orption isotherms: Freundlich and Langmuir. Freundlich isotherms have the form: linear or non. Isotherms with N is a dimensionless empirical constant. Generally, isotherms with orption isotherms: Freundlich and Langmuir. Freundlich isotherms have the form: linear or non. Isotherms with linear case, sorbed-phase and solvent-phase solute S_{max} :

$$S = \frac{S_{\text{max}} k C_w}{1 + k C_w} \quad (13)$$

where k is an empirical constant [$L^3 t^{-1}$].

For steady-state water flow, homogeneous media, and linear sorption, the ADE can be simplified by substitution of Eq. 11 into Eq. 10 resulting in the following equation:

$$R \frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial z^2} - v \frac{\partial C}{\partial z} \quad (14)$$

where $v = \text{eq}_w / \theta$ is the solvent pore velocity and R is the retardation factor, given by

$$R = 1 + \frac{\rho_b}{\theta} K_d \quad (15)$$

for non-reactive solutes [K_d or non-R or non-reactive solutes (r , given by $\rho_b K_d$ increases)], R increases and is a measure of the degree of retardation for sorbed solutes.

Eq. 14 has been solved analytically for a variety of boundary conditions (e.g., Wierenga, Parker and van Genuchten, and Huang and van Genuchten^[4-6]). These solutions can be used to describe solute concentration distributions as a function of space or time. Solutions to more complex applications of the ADE such as transient flow conditions, irregular system geometries, and fluid or media heterogeneities require numerical solution techniques. Gray and Pinder^[7] outlined the fundamental principles of numerical modeling of solute transport. Two broad categories of numerical modeling techniques are available, finite difference and finite element.

NONEQUILIBRIUM SORPTION

Observations that the ADE did not replicate a variety of observed concentration distributions led to the development of nonequilibrium transport theories for both chemical and physical phenomenon. Breakthrough curves for nonequilibrium systems are asymmetric because some solute molecules behave ideally, moving rapidly through the system, while others are slowed due to either chemical or physical interactions with the soil.

Physical non-equilibrium results from the partitioning of the flow field into mobile and immobile regions.^[8] Solutes are advected and dispersed in the mobile regions, while the immobile region acts as a source/sink that exchanges solute mass with the mobile region via diffusion. van Genuchten and Wierenga^[9] developed an analytic solution to the physical non-equilibrium steady-state flow problem for reactive solutes.

Chemical non-equilibrium results from the existence of sites within the soil matrix where sorption and desorption are rate-limited. A two-site model has been proposed^[10,11] where some of the sorption sites are in equilibrium with the soil solution while others share a kinetic relation with the soil solution. Lindstrom and Narasimhan^[12] developed analytical solutions to the 1-D non-equilibrium ADE. An alternative to the two-site model approach is to consider the sorption sites as exhibiting a distribution of rate constants. This technique accounts for the heterogeneity of sorption mechanisms and kinetic rates in the soil system without increasing the number of required model parameters.^[13]

TRANSFER FUNCTIONS AND SOLUTE MOVEMENT THROUGH SOIL

Alternatives to the ADE methodology for modeling the movement of solutes through soil have been proposed.

For example, transfer functions have been proposed to describe solute transport without the constraint of describing the causative transport processes, instead shifting the focus to characterizing the output from the system.^[14] The transfer function approach requires knowledge of the input solute distribution and the general nature of the output solute distribution. With this knowledge, the solute concentration exiting the soil system can be determined at any distance from the input location. Innovative approaches to modeling the movement of solutes through the soil system will continue to be the primary focus of soil and environmental physics.

Spectral Mixtures: Soil—Plant

Alfredo R. Huete

*Department of Soil, Water and Environmental Sciences, University of Arizona,
Tucson, Arizona, U.S.A.*

Abstract

Approximately 70% of the earth's terrestrial surface consists of open canopies with vegetation overlying various proportions of exposed soil and litter background. The aim of remote sensing is to exploit and model these complex patterns of surface energy interactions for the purpose of mapping and extracting information about the biophysical and biochemical character of soils. Several approaches are used to analyze soil-plant spectral mixtures, including vegetation indices (VIs) and mixture models. VIs are useful in assessing the spatial and temporal dynamics of the vegetation component but yield little information on soil type and soil properties. Mixture models, on the other hand, have been successfully used to discriminate and monitor both soil and vegetation biophysical properties from broadband multispectral sensor systems to hyperspectral sensor imagery. Hyperspectral sensors have greatly improved the identification of numerous soil and plant absorption features.

INTRODUCTION

There exists considerable knowledge about soil optical properties based on extensive laboratory analyses studies.^[1–3] Information about soils are generally obtained by analyses of their spectral signatures, which are a function of the absorption properties of their biogeochemical constituents, moisture condition, and the size, shape, and geometry of the soil particles. At the landscape level, it is much more difficult to monitor and assess soil properties due to their extreme spatial variability and the masking of the soil surface by vegetation and litter. Airborne and satellite remote sensing are used to characterize and map soils in several ways: 1) direct remote sensing measurements of exposed soil surfaces in vegetated (e.g., canopy gaps) and non-vegetated areas (hyperarid zones); 2) employment of spectral mixture models to generate soil component images from remote sensing data over partially vegetated areas; and 3) one can infer soil properties based on remote sensing measurements of the overlying vegetation.

SOIL-VEGETATION CANOPY MIXTURES

In arid, semiarid, and subhumid regions, soil surfaces are rarely spectrally pure and often contain significant quantities of litter and vegetation mixing with the soil signal.^[4] The remotely sensed, spectral responses from these surfaces are a function of the number and type of reflecting components, their optical properties, and their relative proportions. The optical properties and mixture proportions further vary seasonally and with land cover conversions.^[5] Resolving the extent of soil and vegetation cover is important to hydrologic and biogeochemical processes and crucial for functional analyses of ecosystems.^[6–8]

BASICS OF MIXTURE MODELING

Spectral mixture models are used in remote sensing to separate remote sensing measurements into their soil, non-photosynthetically active vegetation (NPV), and vegetation components. Such models have utility in a variety of applications, including biogeochemical studies, leaf water content, land degradation, land cover conversions, fuelwood assessment, and soil and vegetation mapping.^[9–12] Soil-plant spectral mixtures may be modeled as linear or non-linear mixtures.^[13,14] In the linear case, also known as the “checkerboard” model, photons only interact with a single material and the fractions of each material are equivalent to their aerial proportions.^[15] Linear models are easy to use and work quite well over certain types of land cover conditions, such as desert shrub canopies.^[16] Mixture modeling generally involves three steps:

1. assess the dimensionality or number of spectral constituents in an image;
2. identify the physical nature of each of the constituents or “endmembers”;
3. derive the amounts of each component for each pixel in the image.

The first step is generally accomplished with principal components analysis. The second step is achieved with an end-member analysis whereby various reference spectra are used to model the image. Several types of endmember signatures may be utilized in spectral mixture analyses, including image endmembers, bundled spectra endmembers, and laboratory reference endmembers, which are cataloged in “spectral libraries”^[17] (Fig. 1). Typical endmembers used in remote sensing include green vegetation, soil, NPV, and

Fig. 1 Examples of reference spectral signatures of soil–plant components commonly found in semiarid canopies of the southwest United States.

“shade.” Shade is used to model pixels not fully illuminated and vary with topography.^[18]

In matrix notation, a linear mixture model is expressed as follows:

$$[D]=[R][C]+[\epsilon], \quad (1)$$

where $[D]$ is the spectral data matrix, $[R]$ is the reflectance matrix of the spectral constituents (endmembers), $[C]$ is the component contributions or “loadings” matrix, and $[\epsilon]$ is the residual errors. One can first model the spectral variability of a scene with several image endmembers followed by the use of reference endmembers to determine the composition of the image endmembers.^[19] Residual images are a quick way to find “outlying” pixels not adequately explained by the mixture model and may indicate the presence of unknown reflecting components. Residuals in the short-wave infrared region, attributable to cellulose and lignin in the vegetation, have been used to resolve and separate the NPV signal from soil.^[20] Residual images also contain the bulk of the noise and error in images. The products of mixture modeling include a set of component fraction images and a set of residual images containing the differences between modeled and measured data.

HYPERSPECTRAL SENSORS

Hyperspectral imaging sensors, with a large number of contiguous bands, carry valuable diagnostic information about soil and vegetation surfaces and have great potential for quantitative retrieval of their biophysical properties. The airborne visible–infrared imaging spectrometer (AVIRIS) sensor is of particular interest in soil–vegetation spectral mixture studies. AVIRIS operates in the 400–2450 nm region collecting 224 spectral bands with a nominal 10 nm spectral response function.^[21] This enables one to observe high-resolution spectra associated with unique absorption features, which are typically lost in

coarser waveband data, such as from Landsat thematic mapper (TM), SPOT, and AVHRR. The Hyperion Hyperspectral Imager onboard the Earth Observing-1 provides 220 contiguous bands covering the spectrum from 400 to 2500 nm.^[22] This sensor is a part of NASA’s New Millennium Program, Earth Observing series designed to test new technologies for Earth System Science studies.

Okin et al.^[23] used AVIRIS data in retrieving soil and vegetation information in arid and semiarid environments. They applied a multiple endmember spectral mixture analysis on AVIRIS imagery collected over the Mohave Desert in California and were able to reliably distinguish and map soil-surface types and vegetation cover. Palacios-Orueta et al.^[24] used hyperspectral AVIRIS imagery to map the spatial variation of soil organic matter and soil iron contents over two watersheds in the Santa Monica Mountains in California. They used a sequential spectral mixture analysis technique known as hierarchical foreground/background analysis to limit the influence of the vegetation signal while extracting the variation in the soil signal with laboratory derived “training” vectors.

INFERRING SOIL PROPERTIES THROUGH VEGETATION

About 25–30% of the land area have significant quantities of forest and dense vegetation with leaf area index values exceeding 1, including tropical and temperate forests and cropland. Where the surface is strongly vegetated, soil properties must be inferred from measurements of the vegetated surface in conjunction with models and field measurements. Spectral vegetation indices (VIs) as well as mixture models have been used to map vegetation characteristics to infer soil properties. Cwick et al.^[25] mapped the forest soils in Manitoba through hyperspectral reflectance measurements of Black Spruce (*Picea mariana*) needles.

They utilized the concentrations of potassium in the needles to infer the potassium distributions in the soil rooting zone with primary variations associated with either poorly or well-drained soils.

CONCLUSION

Approximately 70% of the earth's terrestrial surface consists of open canopies (deserts, grasslands, savannas, and open forests) with vegetation overlying various proportions of exposed soil and litter background.^[4] The aim of remote sensing is to exploit and model these complex patterns of surface energy interactions for the purpose of mapping and extracting information about the biophysical and biochemical character of soils. Several approaches are used to analyze soil-plant spectral mixtures, including VIs and mixture models. VIs are useful in assessing the spatial and temporal dynamics of the vegetation component but yield little information on soil type and soil properties. Mixture models, on the other hand, have been successfully used to discriminate and monitor both soil and vegetation biophysical properties from broadband multispectral sensor systems (Landsat TM, SPOT, and AVHRR) to hyperspectral sensor imagery (AVIRIS, Hyperion). Hyperspectral sensors have greatly improved the identification of numerous soil and plant absorption features, from soil-plant mixtures, related to mineralogy, liquid water, chlorophyll, cellulose, and lignin contents.^[1,7,9]

Spodosols

Delbert Mokma

Department of Crop and Soil Sciences, Michigan State University, East Lansing, Michigan, U.S.A.

Abstract

Spodosols have a typical morphology, dark colored O or A horizon, ashy gray colored albic horizon, and dark reddish brown colored B horizon. Organic compounds formed by decomposition of organic matter in the surface form organo-metallic complexes with aluminum and iron that are released by weathering of minerals in the subsurface. These complexes accumulate and coat sand grains in the B horizons and may cement grains together into ortstein. The degree of Spodosol development is determined by parent material, topography, vegetation, climate, and time.

INTRODUCTION

Spodosols are a group of soils that are characterized by the presence of a spodic horizon in which active amorphous organic matter and aluminum (Al), with or without iron (Fe), have accumulated.^[1] The formative element of the word, “Spodosols,” was derived from the Greek word, “spodos,” which means wood ashes. The name is connotative of bleached eluvial (E) horizons that overly distinctive reddish brown spodic (Bhs or Bs) horizons. Most Spodosols are sandy. These materials have many macropores and are rapidly permeable. Sandy properties give Spodosols low available water capacities. Available water capacity increases as the amount of humus and sesquioxides in the spodic horizons increases.^[2] Cation exchange capacity is related to the amount of organic carbon (C) rather than clay. Spodosols are acidic, thus they are naturally infertile.

A typical Spodosol has a distinctive profile with four master horizons (Table 1). O and/or A horizons have black or dark brown colors, which result from accumulation of organic materials. E horizons have ashy gray color albic materials,^[1] as a result of the weathering of the non-resistant minerals and subsequent eluviation of amorphous materials. The Bhs or Bs horizons have dark reddish brown colors resulting from illuvial accumulations of organo-metallic complexes. Reddest hues, darkest values, and lowest chromas usually occur in upper parts of spodic horizons. Dark reddish brown colors of spodic horizons are related to amounts of amorphous materials.^[3] Hues become more yellow, and value and chroma increase with depth. Colors of C horizons tend to have yellower hues and higher values than spodic horizons.

Primarily, E horizons have uncoated sand grains. Immobilized, organo-metallic complexes coat most sand grains in B horizons. These coatings become thicker with time. As vegetation removes water from B horizons, desiccation

causes cracks to form in the coatings. Thin Al and/or Fe oxide coatings occur on sand grains in C horizons.

DISTRIBUTION

Spodosols are most extensive in areas of cool, humid, or perhumid climates.^[1] Some have formed in warm and hot, humid regions especially in areas of quartz-rich sand that have fluctuating water tables. Spodosols are not formed in arid areas.

FORMATION OF SPODOSOLS

Soil-Forming Processes

Translocation of humus and sesquioxides

Formation of Spodosols involves the formation, translocation, and immobilization of organo-metallic complexes. Organic acids form in forest canopies, canopy leachate, and soil organic matter. These acids cause weathering of minerals and release of Al and Fe in upper mineral horizons. Soluble organo-metallic complexes form and move downward through O and A horizons. Al and Fe in several Swedish and Finnish Spodosols are translocated downward as organo-metallic complexes.^[4]

Immobilization of organo-metallic complexes occurs as a result of increases in pH, microbial decomposition of the organic ligand, and when the amount of Al and Fe taken up by organic molecules exceeds a threshold. Vanillic and p-hydroxybenzoic acids dominated surface horizons of Spodosols in Michigan, whereas protocatechuic acid dominated spodic horizons.^[5] Distribution of protocatechuic acid paralleled those of Al and Fe, suggesting that it plays a role in the translocation process.

Table 1 Selected properties of a typical haplorthod.

Horizon	Depth (cm)	Texture	Color	Organic C (%)	ODOE ^a	Al ^b (%)	Fe ^b (%)
A	0–8	S	10YR 3/1	1.8	0.02	0.04	0.05

^aOptical density of oxalate extract.^bExtracted with ammonium oxalate.

Ortstein is a spodic horizon in which sand grains are cemented together by organic matter and Al with minor amounts of Fe and little or no silicon.^[6] Ortstein in somewhat poorly drained Spodosols usually have horizontal orientation, whereas that in well-drained Spodosols usually have vertical orientation.^[7] Ortstein in the former soils is more continuous and more strongly cemented, thereby being more root restrictive than the later soils. Ortstein reduces forest and blueberry production. Crushed ortstein receiving blueberry leaf extract recemented in 10 days in a laboratory study.^[8] Tillage operations to break ortstein are not likely to be permanent solutions. Crushed ortstein receiving blueberry and white pine leaf extracts recemented more completely and more strongly than bracken fern leaf extract.^[9]

Silicon

Silicon may play a role in the translocation of Al through the formation of imogolite.^[10] Imogolite tends to be greater in lower Bs horizons than in upper Bhs or Bs horizons. It may form in spodic horizons after Al had been translocated as organo-metallic complexes,^[11] which may be broken down by soil microbes, thereby releasing ionic Al. The Al could then form imogolite in the B horizon.

Soil-Forming Factors

Parent material

Spodosols developed in sandy to coarse loamy materials. They usually have little silicate clay. Quartz is the primary mineral in sand and silt fractions, with lesser amounts of orthoclase, plagioclase, mica, pyroxene, and amphibole.^[12] Accessory minerals are often highly weathered and are not easily identifiable. Less resistant minerals tend to have weathered from E and B horizons.

As clay content of parent materials increases, the translocation of organic C, Al, and Fe decreases, thickness of E and B horizons decreases, and B horizon color is lighter and less red.^[13] Silicate clays inhibit translocation of organic C, Al, and Fe by adsorbing these materials.

Topography

Spodosols form on surfaces that have shallow to very deep water tables. Spodic horizon development is influenced by depth and duration of water saturation.^[14] Spodic horizons do not readily form in soils that are saturated with water near the soil surface for long periods. Water saturation inhibits translocation processes. Poorly drained soils in Spodosol landscapes usually have less organic C, Al, and Fe in their B horizons than better-drained Spodosols in the hydrosequence. Some poorly and somewhat poorly drained Spodosols, especially those in warmer climates, have little Fe because it is chemically reduced and leached from the soil. Somewhat poorly drained Spodosols usually have more humus and sesquioxides than other members of the hydrosequence. Saturated zones inhibit water movement, thus, organo-metallic complexes are carried from A and E horizons to B horizons, but rarely through B horizons. In well-drained Spodosols, organo-metallic complexes can be carried by percolating waters to and through B horizons to lakes and streams.

Vegetation

Spodosols form under coniferous and deciduous forest but not under grasses. Spodic horizons formed under conifers have more Al and Fe than those under deciduous trees.^[15] Because organic compounds are involved with translocation of Al and Fe, more leaf or needle litter means more organic compounds available to form organo-metallic complexes.

Fire frequency influences spodic horizon development by affecting forest succession.^[16] When intervals between intense fires are 5 and 50 years, jack pine (*Pinus banksiana* L.) survives and regenerates. Much organic matter on the forest floor is destroyed by frequent fires; therefore, less organic compounds are available to form organo-metallic complexes with Al and Fe. Thus, E horizons are thin or non-existent, and B horizons have small amounts of organic C, Al, and Fe. If fire intervals are 50–350 years, white (*Pinus strobus* L.) and/or red (*Pinus resinosa* Ait.) pine succeed jack pine. Less organic matter is destroyed by fewer fires and more organic compounds are available to form complexes with Al and Fe and translocate them from

E horizons to B horizons. If fire intervals exceed 350 years, northern hardwoods (sugar maple, *Acer saccharum* Marsh; beech, *Fagus grandifolia*) succeed the pines. These trees are more shade tolerant and more fire resistant. Translocation of organic C, Al, and Fe continues, but more slowly because less Al and Fe and more Ca are biocycled.

Climate

Spodosols usually form in areas with cool, humid climates. Spodosols of warmer climates have less Fe compared to those of cool climates. Spodosols dominate areas with cryic and frigid soil temperature regimes but are less common in areas with a mesic soil temperature regime in New England.^[17] Strong spodic horizon development is associated with areas of deep snowpack before soils freeze in Michigan. Meltwater from snow can freely percolate through the soil in spring.

Time

Under optimum conditions Bs horizons may form in few 100 years, but usually they form more slowly. Eluvial horizons form in 300 years or less.^[18,19] Weak Bs horizons form in about 2000 years.^[19,20] At least 8000 years are required for most soils on a surface to qualify as Spodosols.

CONCLUSION

Spodosols have a typical morphology, dark colored O and/or A horizon, ashy gray colored albic horizon, and dark reddish brown colored B horizon. Organic compounds formed by decomposition of organic matter in the surface form organo-metallic complexes with Al and Fe that are released by weathering of minerals in the subsurface. These complexes accumulate and coat sand grains in the B horizons and may cement grains together into ortstein. The degree of Spodosol development is determined by parent material, topography, vegetation, climate, and time.

Strontium

Silvia H. Haneklaus

Ewald Schnug

Institute for Crop and Soil Science, Julius Kuhn Institute (JKI), Braunschweig, Germany

Abstract

The contamination of soils, plants, and water bodies with radionuclides is a major threat to human health. Contaminations with radioactive strontium (Sr) are particularly dangerous because of its similarity to calcium (Ca). Experiments on the behavior of radioactive Sr in the soil, its transfer to the food chain, and its interactions with Ca are limited. A solution to this problem is the analysis of stable Sr, which behaves identically to radioactive Sr. This contribution summarizes data on chemical speciation and spatial variability of Sr in soils, its relationship with relevant soil parameters, and factors influencing Sr uptake by plants. Special attention was paid to Ca, as it has to be put on par with Sr.

INTRODUCTION

Strontium (Sr) was discovered by Adair Crawford in 1790 and named after the Western Scottish village of Strontian. There are four stable Sr isotopes, namely, ^{84}Sr , ^{86}Sr , ^{87}Sr , and ^{88}Sr , which occur naturally in a ratio of 0.56:9.87:7.00:82.58, respectively.^[1] Of these four stable Sr isotopes, only ^{87}Sr is radiogenic. Thus, the ^{87}Sr concentration increases over time because of the decay of rubidium (^{87}Rb) to ^{87}Sr (half-life of 4.7×10^{10} yr). However, the radioactive isotope ^{90}Sr from anthropogenic nuclear sources is commonly associated with ^{87}Sr . Plant available concentrations of Sr and calcium (Ca) in soils are important factors that affect the transfer_{soil/plant} of ^{90}Sr .^[2] Consequently, the knowledge of the factors and processes influencing the chemical and spatial speciation of Sr in the soil is of prime interest in risk assessment of undesired ^{90}Sr contaminations.

Sr IN SOILS

Sr occurs abundantly in nature, and its concentration can be as much as 0.034% in most igneous rocks.^[3] Celestite (SrSO_4) and strontianite (SrCO_3) are the predominant Sr minerals. It occurs in large concentrations and in association with potassium in volcanic rocks, alkali rocks, and pegmatites. Sr is removed by weathering from these and other igneous rocks and sediments. Intermediate concentrations of Sr occur in basic magmatic rocks, which contain about two times higher Sr concentrations than granite. Some ultramafic rocks have very low Sr concentrations.^[4] A mean Sr concentration of 375 mg kg^{-1} is observed in igneous rocks, 300 mg kg^{-1} in shales, and 20 mg kg^{-1} in sandstones.^[5]

Sr isotope ratios in parent materials and minerals vary in relation to geological age and geographical location.^[6]

The $^{87}\text{Sr}/^{86}\text{Sr}$ ratio depends on the initial Rb/Sr ratio in the parent material, the age of rock, and the Sr isotope ratio at the onset of rock formation, as ^{87}Sr is radiogenic.^[6] The $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is often used to study biogeochemical processes such as weathering of minerals. However, this ratio must be evaluated critically, as with the age of weathering, surface changes in the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio also occur, presumably because of dynamic variations in weathering rates of different minerals.^[7]

In the soil profile, about 90% of the Sr is generally exchangeable and 10% in non-exchangeable form.^[8] The data in Table 1 summarize total and plant available Sr concentrations in soils of different origins. Reimann et al.^[4] reported distinctly lower total Sr concentrations in soils of northern Europe with a median of 110 mg kg^{-1} Sr in comparison with the world average of 240 mg kg^{-1} Sr. In several countries of northern Europe, median values for total Sr concentrations range from 45 mg kg^{-1} in Poland to 181 mg kg^{-1} in Norway. About 7% of the total Sr concentration in the topsoil is plant available.^[4] The reported plant available Sr concentrations range from 4 mg kg^{-1} in Poland to 15 mg kg^{-1} in Finland.^[4] The corresponding values for Germany are 8 ($\text{NH}_4\text{-Ac}$) and 55 (total) mg kg^{-1} Sr, and somewhat lower than those reported by Haneklaus^[2] in Schleswig-Holstein with 18 ($\text{NH}_4\text{-Ac}$) and 79 (total) mg kg^{-1} Sr (Table 1). The mean rapidly exchangeable Sr concentration in these studies was 4.8 mg kg^{-1} Sr.

Interaction of Sr with Soil Matrix

The advantage of using stable Sr in research is that it provides a direct measure for the spatial variation of pedogenetic soil characteristics and agro-technical measures influencing the uptake of radioactive Sr isotopes by plants. In comparison, studies with radioactive Sr (viz. ^{90}Sr , ^{89}Sr ,

and ⁸⁵Sr) provide *in situ* analysis of radioactive Sr behavior under existing soil conditions. An important point to be noted in Sr experimentation is whether the stable or carrier-free radioactive Sr has been used, which leads to the application of significant amounts of Sr in the former case, compared with only insignificant rates of Sr added to the soil in the latter case.

The correlation matrix between soil pH, clay, organic C, plant available Ca concentration, and Sr species is shown in Fig. 1 for soils from the federal state of Schleswig-Holstein.^[2] Correlation coefficients between total exchangeable Sr and C_{org.} were significant but low. In comparison, distinctly close and significant relationships were observed for soil pH and clay content (Fig. 1). Reimann et al.^[4] and Haneklaus^[2] also reported a similar correlation coefficient of $r = 0.6$ for the relationship between total Sr and NH₄-Ac extractable Sr when total Sr was determined by aqua regia extraction and X-ray fluorescence (X-RF) techniques, respectively. Analogous correlation coefficients were also observed for the relationship between plant available Ca ($r = 0.78$) and plant available Sr ($r = 0.90$) concentrations in the topsoil (Fig. 1).^[2,4]

Rengel estimated a mean Ca loss of 300 kg ha⁻¹ yr⁻¹ by leaching. The Ca/Sr ratio in soils is about 140 for total^[15] and may vary between 250 and 5000 for exchangeable Ca and Sr.^[16] Assuming equivalent leaching rates of Ca and Sr implies Sr losses of <1 kg ha⁻¹ yr⁻¹. Wiklander^[8] observed considerable leaching losses of ⁹⁰Sr in a lysimeter experiment after 42 months.

Sr sorption is dominated by ion exchange, and sorption/desorption is a reversible process; the organic soil fraction preferentially adsorbs Ca, while the inorganic soil fraction (e.g., the clay minerals) preferentially adsorbs Sr.^[17,18]

Fig. 1 Correlation between soil parameters and Sr species in topsoil samples of production fields in northern Germany (n=155).
Source: Calculated from data by Haneklaus.^[2]

A small fraction of ^{85}Sr added to the soil is also fixed in non-exchangeable form. Valcke^[17] suggested that this fixation occurs in Sr/organic matter/clay complexes.

The adsorption of Sr on different types of clay minerals has been studied intensively with the objective to decontaminate effluents from contaminated sites. Sr is adsorbed moderately to mineral surfaces and is desorbed when its concentration in the soil solution increases, competing ions such as Ca are present, and soil pH is low.^[19] The application of even small quantities of stable Sr and Ca as amendments may increase the uptake of ^{90}Sr by desorption. However, the application of Ca may positively increase the Ca/Sr ratio.^[20] The Sr sorption decreases in the presence of calcite, and high concentrations of bicarbonate and SrCO_3 may be formed at high concentrations of Sr in the soil.^[19] For a Cambrian blue clay soil, the Langmuir isotherm indicated a constant of 294 and a limiting sorption of $0.034 \text{ mol kg}^{-1}$.^[18] Also Freundlich isotherms reflected an adequate sorption of Sr with a regression coefficient of >0.99 . The sorption ratio is generally higher than 0.95 for all concentrations ranging from 10^{-3} to 10^{-8} M .^[21]

Sr UPTAKE BY PLANTS

Sr uptake by plants is passive and is thus linked to its concentration in the soil solution. Plant available Ca and Sr in the soil are important factors governing the uptake of radioactive Sr. The addition of Ca often results in a negative linear relationship between Sr and Ca in plants.^[2] The Sr to cation exchange capacity (CEC) ratio influences Sr uptake in such a way that any increase in the CEC decreases the Sr uptake.

The Sr concentration in plants varies depending on the plant available concentrations in the soil, root uptake, and the growth or phenological stage. Sr uptake by dicotyledonous crops is, e.g., distinctly higher than that by monocotyledonous crops owing to the higher CEC of the latter.^[20] The Sr concentration in vegetative plant tissue varies between 1 and 150 mg kg^{-1} with a mean value of

25 mg kg^{-1} .^[3] The Sr concentration in seeds is about 5 to 10 times lower than that in vegetative plant material, most likely because of the phloem immobility.^[20] Sr concentrations from 18 to 36 mg kg^{-1} have been reported in oilseed rape seeds, while the average concentration was 7 mg kg^{-1} in wheat.^[2]

Impact of Fertilizer Use on Sr Uptake by Plants

Gabe and Rodella^[22] reported Sr concentrations in different phosphatic fertilizers, limestone, and gypsum. The mean Sr concentration (mg kg^{-1}) occurs in the following order: concentrated apatite (12,121) > rock phosphates (7319) > single super phosphate (5396) > fused phosphates (4965) > gypsum (2984) > limestone (824) > ammonium phosphates (304). The variation in the Sr concentration was the highest in limestone samples ranging from 36 to 4736 mg kg^{-1} Sr. Long-term application of lime significantly increased soil pH along with total Ca and Sr concentrations in an acid Albic Luvisol in Romania (Fig. 2).^[23] Haneklaus^[2] reported that the Sr uptake in plants is influenced more by the Ca concentration in soil rather than by soil pH. Liming of an acid soil can reduce the Sr uptake by 40–45%, as was reported in a lysimeter experiment by Wiklander.^[8] Under field conditions, Haneklaus^[2] estimated a minimum threshold rate of lime application of 1.4 t ha^{-1} CaO for reducing the Sr uptake significantly on an acid, silty loam soil (pH 5.3). Liming combined with an additional Ca supply by gypsum can cause the maximum reduction in Sr uptake by oilseed rape probably because of the precipitation of SrSO_4 .^[2] In contrast, Andersen^[20] reported that a dose of at least 10 t ha^{-1} stable Sr is required to achieve a significant reduction of ^{90}Sr uptake.

CONCLUSION

Sr behavior in soils and uptake by plants are similar to that of Ca. Stable Sr is usually of minor interest, but it may gain

Fig. 2 Long-term influence of regular lime applications of 0, 5, and 10 t ha^{-1} from 1961 to 1998 corresponding to total rates of 0, 30, and 60 t ha^{-1} on soil pH and total Sr and Ca contents in the topsoil of an Albic Luvisol in Romania.

relevance with its role in reducing the transfer of radioactive Sr into the food chain. An optimum Ca saturation is a prerequisite to limit the uptake of radioactive Sr by plants. Furthermore, amendments (e.g., lime) add significant amounts of Sr to the soil and thus increase the concentration of competitive stable Sr in soils.

Structure

Eileen J. Klavivko

Agronomy Department, Purdue University, West Lafayette, Indiana, U.S.A.

Abstract

Soil structure is an important characteristic of the soil. There is no one single definition of soil structure, but most descriptions of structure refer to the “arrangement” (size, shape, and orientation) of particles and the pores between them, or the “stability” of the particle arrangement to some disruptive force (e.g., hand manipulation, water, wind, and wheel traffic). Soil structure affects many properties and processes in the soil.

INTRODUCTION

Soil aggregates are the backbone of soil structure. Aggregates are clusters of organic matter, sand, silt, and clay held together by a variety of forces. A hierarchical order of aggregates is sometimes described with smaller groupings of particles comprising microaggregates and then groupings of microaggregates forming macroaggregates.^[1,2] Pores within aggregates are smaller and are important for water retention, whereas pores between aggregates are larger and are important for water flow and aeration.

DESCRIPTION OF STRUCTURE

The descriptions of soil structure are often approached from the viewpoint of pedology, plant growth, or physics. The pedological view describes the shape, size, and relative strength of soil peds or aggregates. These descriptions reflect long-term soil forming processes as well as shorter-term human-induced changes caused by soil management practices.

From an agronomic point of view, “good” soil structure promotes rapid water infiltration, adequate drainage of excess water, good aeration, water retention, resistance to erosion, and good germination, emergence, and rooting of plants.^[3] “Poor” soil structure may result in surface crusting, decreased infiltration, increased runoff and erosion, poor seedling emergence, poor rooting ability, or inadequate air or water for plants. Much of the soil management research conducted over the decades has been to devise ways to improve soil structure while enhancing cash crop yields.

The soil physics view of soil structure is often to assess the stability of aggregates to disruptive forces that simulate disruptive forces in the field.^[2] Size distribution and stability of aggregates after disruption are used to calculate quantitative indices of stability. Other ways to describe structure include pore size distribution and continuity. The particular

method used to assess or describe soil structure should be matched with the intended use of the information.

AGGREGATE FORMATION

Soil aggregates are formed through biological, chemical, and physical processes. As soil microorganisms decompose plant residues and other organic materials, they exude polysaccharides that tend to glue particles together. Fungal hyphae also enmesh particles, thereby forming aggregates. Earthworms help to aggregate soil through excretion of mucilages, which stick particles together, as well as bringing mineral and organic particles together in their castings. Plant roots also help to aggregate soil through several mechanisms, including root exudation and physical enmeshment by fibrous roots. Chemical conditions that impact aggregation include the concentrations and types of cations present in the soil solution, as they affect flocculation of the clay particles. Physical processes affecting aggregation include wetting/drying cycles, freeze/thaw cycles, and mechanical tillage. These physical processes break down large clods and destroy aggregates, but they also bind particles together to form small aggregates. The net impact of these physical processes on formation and destruction of aggregation is highly dependent on initial soil conditions.

An important point to remember is that soil aggregation is dynamic.^[2,3] Aggregates are not permanent but are continuously being created and destroyed by natural means as well as by human management of the soil. Soil management practices must include regular “maintenance” of soil structure to sustain productivity over the long term. For example, soils maintained as native grasslands generally have higher organic matter contents and greater aggregate stability than similar soils used for row crop production.^[4] When soils are used for crop production, sustainable management practices often include periodic inputs of organic materials (animal manures and crop residues) to the soil to

provide a food source for the soil organisms which in turn form aggregates. The relative stability of different organic binding agents in soil micro- and macroaggregates is discussed in more detail in other sections of this encyclopedia. Growing a fibrous-rooting plant as a cover crop after the main crop is harvested is a way to use the normally fallow time periods of the year to improve near-surface structure. Conservation tillage practices, especially no-tillage, are another way to improve soil aggregation and stability compared with conventional tillage practices.^[5] The increased aggregation results from both greater aggregate formation near the surface, because of the presence of surface crop residues, and less physical disruption of aggregates by the tillage operation itself.

ENVIRONMENTAL SIGNIFICANCE OF SOIL STRUCTURE

Stable soil aggregates contain organic binding agents, as discussed earlier, and therefore are involved in carbon sequestration in soils. Within a given soil, increased soil aggregation is usually associated with increased soil carbon. Conversely, as aggregates are disrupted or destroyed, carbon mineralization and carbon dioxide evolution increase.^[6] Therefore, increasing soil aggregation and aggregate stability can be an important method to increase carbon sequestration in soil. It must be remembered, however, that these higher aggregation levels must be continuously maintained, as previously discussed, or else the sequestered carbon will be released again. Soil organic matter associated with different aggregate size fractions appears to have different turnover times, and the interplay of organic matter chemistry, aggregate size, and physical location within or between aggregates is active areas of research.

Although aggregates are naturally degraded with time as microorganisms feed on the organic binding materials, these are more quickly and noticeably destroyed by tillage operations. Aggregates near the soil surface are also subjected to the disruptive impact of raindrop energy or rapid wetting, which can result in slaking, dispersion, and crust formation. Such surface structural breakdown can have major impacts on plant growth and overall soil functioning. Surface crusts can delay or inhibit seedling emergence, leading to low plant populations and yields. Surface seals can also reduce infiltration and increase runoff and erosion. The partitioning of less water into the soil profile may reduce water availability to the plant at a later date. The structure of soil below the surface may be degraded by tillage or wheel traffic, with potential consequences of poor rooting ability because of compaction, poor drainage and aeration of the rooting zone, and reduced water availability to the plant.

The structure of surface and subsurface horizons affects water flow into and through soil profiles and across landscapes. The partitioning of water between infiltration and surface runoff is controlled largely by near-surface conditions, although subsurface impeding layers may limit infiltration as well. Impeding layers may occur naturally or be formed as a result of management. In fields with a good subsurface drainage system, e.g., water collects temporarily in depressions after a rain. If these depressions are tilled when the soil is too wet, near-surface soil horizons become compacted and impermeable. After the next rain, water stands in these depressions even longer because of the compacted soil. Many soils have sufficient structural development below the surface to exhibit some degree of preferential flow of water, whereby water flows quite rapidly through large, interpedal voids while moving more slowly into and through smaller pores within the aggregates.

CONCLUSION

In summary, it is well known that soil structure has a major influence on the ability of soil to perform different functions. Whether the soil is used to grow plants, accept wastes, or partition rainfall into runoff, or for interflow, groundwater recharge, or build houses and roads, the arrangement of particles and the stability of that arrangement are important factors to consider. Research attempts to more quantitatively describe the *in situ* structure and the response of soil to various disruptive forces, as well as the relationships between soil structure, plant growth, and water flow.

Structure: Belowground Management

Ken A. Olsson

Tatura, Victoria, Australia

Bruce Cockroft

Research Consultant, Kialla, Victoria, Australia

Abstract

Researchers have long sought to improve the structure of difficult subsoils by deep tillage, chemical ameliorants, and ameliorative crops, aiming for higher yields through faster infiltration of water, deeper wetting, increased water and nutrient availability to plants, increased drainage, leaching of salts and toxins, lower soil strength, and deeper rooting. Subsoil modification, however, has not consistently increased crop yields, while benefits are often transient and confounded. Many ameliorative measures do not modify the subsoil to a particular specification, while most do not adequately address the stabilization and subsequent management of the modified soil.

INTRODUCTION

Crop yield is strongly correlated with the production and functioning of roots. Soil management aims to produce and maintain conditions in the soil so that roots are provided with low mechanical resistance, non-limiting supplies of water, oxygen, and nutrients, and favorable soil temperature.^[1] Root growth and functioning are promoted by soil structure of low strength and of high porosity that facilitates the necessary transport of water, nutrients, and gases through stable pores.^[2] While specifications for the necessary levels of soil strength and porosity are well documented,^[1,3] they are not generally met in poorly structured subsoils underlying the surface (A) horizon(s). These include hardpans, claypans, and compacted layers of high strength and low porosity. Such layers limit yield by physically restricting root proliferation, drainage, and the storage and transport of water, while making the management of otherwise well-structured surface horizons both difficult and inflexible.^[4,5]

Researchers have long sought to improve the structure of difficult subsoils by deep tillage, chemical ameliorants, and ameliorative crops, aiming for higher yields through faster infiltration of water, deeper wetting, increased water and nutrient availability to plants, increased drainage, leaching of salts and toxins, lower soil strength, and deeper rooting.^[6] Subsoil modification, however, has not consistently increased crop yields, while benefits are often transient and confounded.^[7–9] Many ameliorative measures do not modify the subsoil to a particular specification, while most do not adequately address the stabilization and subsequent management of the modified soil.

IMPROVING AND MANAGING SUBSOIL STRUCTURE

Principles guiding the improvement and management of subsoil structure for the growth and functioning of roots are documented in the literature.^[10] An initial survey of the soil profile provides information on soil physical and chemical properties including soil horizons, textures, and clay mineralogy. Any chemical problems such as salinity, sodicity, and acidity are corrected and nutrients are supplied at non-limiting rates. When soil temperature is not the limitation, the main soil physical factors that directly influence root growth and functioning are soil strength, soil water supply, and aeration. Specifications for each that is non-limiting for roots are given in the literature.^[1] Management to reduce soil strength and to increase porosity is then based on meeting each of these in a defined volume of soil within the root zone.

Soil Strength

For unrestricted elongation, roots require soil strength, measured as penetrometer resistance, of less than 0.5 MPa.^[11] However, subsoils and compacted layers may have penetrometer resistances greater than 2 MPa, even when wet. In dense clay subsoils, strength increases rapidly on drying and roots may grow only during brief periods and over a small range of matric suction. This results in shallow, confined root systems, and low root concentrations in the matrix.^[10] In expansive clays, roots tend to be restricted to cracks.

Soil strength is reduced by loosening the clay and fragmenting hardpans^[4] while producing macropores (>30 μm diameter). The resulting fragments and aggregates assist root proliferation.^[10] Loosening the soil to about 0.5 m depth is considered a practical compromise in reducing the

effects of dense soil,^[1,3] but the depth of modification will depend on the position of restricting layers within the root zone. Ripping is effective in brittle soils, hardpans, and compact sandy layers; it is less effective in loams and clays. Loosening of clay subsoils is best performed using rigid tines working in soil slightly drier than the plastic limit, aiming to achieve brittle failure.^[12] The tines fail the soil upward by means of low angle tips operating at modest increments of depth and at low speed to avoid high confining stresses at the points. Wings behind each point shear and fracture many of the fragments under the confining pressure from the overburden. Deep tillage may be combined with additions of specified quantities of ameliorants, such as gypsum and lime, to help stabilize the loosened soil.^[10]

An alternative technique mixes the soil layers and incorporates ameliorants, crop residues, and fertilizers in parallel slots, 100–150 mm wide at 1–2 m spacing tilled to the required depth.^[13]

The benefits to crops from changes in soil structure brought about by the activity of roots of previous crop and pasture species are limited in the context. Crop responses are often confounded with improved nutrition and drainage of the surface soil and with reduced incidence of disease.^[14]

The loosened subsoil must be protected from compaction by traffic and from rapid wetting. An effective approach to the problem of soil compaction is to separate roots from traffic using beds.^[15] Management for stability in water and mechanical stability of the loosened subsoil also includes slow wetting and rapid drainage to avoid very low matric suctions to ensure an effective stress within aggregates and fragments.

Loosened subsoils under no traffic inevitably harden with time even though much of the improved macroporosity may be retained.^[16] While roots may grow in the macropores formed by tillage, or by the roots of earlier crops, they may find it difficult to penetrate the hard fragments that are >20 mm diameter where these retain the high strength of the original soil.^[17] A consequent slowing of root growth may be expressed physiologically as a slowing of the shoots, even where supplies of water, oxygen, and nutrients are adequate.^[18] Research is needed to find ways to develop soft, porous aggregates that are stable both in water and to applied mechanical stresses. The process involves the penetration of unconfined fragments by roots and fungal hyphae and mellowing by successive cycles of wetting and drying.^[10] Stabilization requires additions of organic matter from roots, added calcium and electrolyte, and a moist, well-drained environment.

Soil Water

In temperate crops, yield shows a close to linear increase with transpiration.^[19,20] Poorly structured subsoils of low macroporosity slow the infiltration and penetration of water. Subsoils may show a predominance of fine pores (<30 μm diameter), which restrict both the storage and flow of water

to crop roots. Storage pores (0.2–30 μm diameter) in subsoils commonly comprise <15% of the soil volume.^[21,22] Water availability from the subsoil is further reduced where roots have difficulty penetrating the strong matrix. Where topsoils are shallow, potential transpiration rates may be sustained for only a few days after irrigation.^[23]

For rapid water entry, free drainage, and gas exchange, the soil must be stable in water and maintain >15% macropores.^[15] Initially, the fragments produced by tillage may be little altered from the original and limit water storage, gas exchange, and water flow to roots, while mechanically restricting root entry. Should roots become largely confined to and clumped in macropores, they may be poorly functional in water uptake as theory predicts a major resistance to water flow in the soil.^[24,25] Management should aim to develop soft, porous aggregates to enable improved hydraulic properties and a more even distribution of roots. Ideally, these aggregates should have >20% storage pores.^[26]

Soil Aeration

The diffusion of oxygen in air-filled pores continuous to the soil surface is necessary for aeration of the subsoil. Dense, slowly permeable subsoils, however, have few interconnected macropores over depth and may restrict oxygen supply to the root, particularly when the clay is swollen.^[27]

The poor aeration of wet clays slows the growth and functioning of roots^[28] and may also increase the incidence of soil-borne disease.^[29]

Management should aim for a stable air-filled porosity of >15% of the soil volume to be reached within 24-hour drainage throughout the modified solum.^[1] Roots require at least 10% oxygen for unrestricted growth.^[17] Surface drainage is essential. Deep tillage then produces the necessary macroporosity to depth. In some cases, the restructured subsoil in the root zone may connect hydraulically with a more permeable layer beneath.^[1] In other situations, artificial drainage using a pipe or mole drain is required.^[30] In irrigated soils, a slow application rate minimizes filling the macropores with water.

Where fragments and aggregates are not larger than about 10 mm or smaller than 1 mm,^[31] and where the oxygen diffusion rate is higher than about 35 $\mu\text{g}/\text{m}^2/\text{s}$,^[32] intraaggregate aeration is unlikely to be a limiting factor for root growth. An increase in root and microbial respiration in fragments undergoing structural change as described earlier should be met by the increased porosity within the fragment.

CONCLUSION

The management of difficult subsoils to achieve and sustain high productivity from crops must provide the necessary low soil strength together with complements of macropores and storage pores, which will not limit the transfer of water and gases, the proliferation of roots, or the supply of water to crops. Mechanical loosening of dense subsoil layers is an

initial step in an ongoing process of development of the prescribed levels of soil strength and porosity. The process is facilitated by chemical ameliorants, the high initial porosity of the loosened soil, high levels of biological activity, and closely controlled wetting under non-trafficked conditions. A quantitative understanding of root and top responses to profile modification in relation to plant production is an important area for research.

Abstract

Earthworms are an important part of the soil ecosystem and an indicator of soil quality. Sometimes referred to as ecosystem engineers, they play a pivotal role in maintaining soil productivity. Their burrowing, feeding, and casting activities alter the physical, chemical, and biological properties of soil. As a result, earthworms can increase aeration, infiltration, aggregate stability, pH, porosity, and plant-available nutrients. Their abundance and species composition can be affected by soil properties such as pH, texture, water content, and temperature as well as management practices such as tillage, crop rotation and manure, fertilizer, and pesticide applications. The availability of crop residues and other organic materials, which serves as their food source, is usually the most important management factor affecting earthworm abundance. The estimated 3,000–7,000 known species of earthworms can be classified into three ecological groups based on feeding and burrowing habits: litter-dwelling epigeic species, shallow-burrowing endogeic species, and deep-burrowing anecic species. Burrows created by anecic species can play a critical role in facilitating preferential flow of water and agrochemicals through the soil profile. Endogeic and anecic species can accelerate mineralization of plant residues while simultaneously enhancing aggregation and stabilizing organic matter within soil aggregates. Consequently, their net impact on carbon sequestration is uncertain. Earthworm populations and their contributions to soil structure can be maximized by keeping tillage to a minimum, retaining or adding crop residues and manures to soil, and limiting the use of pesticides that are toxic to earthworms.

INTRODUCTION

Earthworms are almost universally regarded by farmers and gardeners as a sign of healthy soil. Entries in farmer-oriented publications frequently include testimonials of how changes in crop and soil management result in the return of earthworms to fields where they were previously absent. The publication of the Soil Biology Primer and the proliferation of websites devoted to earthworms are further recognition of the perceived role of earthworms and other soil fauna in maintaining healthy soils (Table 1). From a scientific viewpoint, however, it is uncertain how much earthworms contribute to soil quality or if they are a consequence or cause of good soil health. Obviously, there are healthy soils that don't have earthworms.

Earthworms affect a number of soil processes including nutrient and carbon cycling, plant growth, and the activity and distribution of microorganisms and are frequently referred to as ecosystem engineers. Perhaps the most noticeable impact of earthworms, however, is their effect on soil structure. Earthworms burrow into and ingest soil and in doing so modify soil porosity, aggregate size, and aggregate stability. The amount of soil ingested is highly dependent on the size, composition, and activity of the earthworm population and is hard to accurately measure because belowground activity is difficult to monitor. Nevertheless, estimated ingestion rates for temperate

region soils are as high as several hundred megagrams per hectare per year. In tropical areas, where climatic conditions are less likely to inhibit activity, ingestion rates as high as 2,600 Mg ha⁻¹ yr⁻¹ have been reported. Similarly, the contributions of earthworms to soil porosity and aggregation, the benefits of earthworm-enhanced soil structure to plant growth, and effects on water quality are difficult to quantify.

TYPES OF EARTHWORMS

Part of the problem in determining the effects of earthworms on soil structure comes from incomplete knowledge of their behavior. Worldwide there are an estimated 3,000 – 7,000 + species of earthworms,^[1] few of which have been investigated in detail. A number of classification schemes have been proposed, which group these species based on various aspects of their behavior. The most widely used system is that of Bouché in which earthworms are divided into three groups.^[1,2] *Epigeic* earthworms are generally found beneath or within accumulations of organic matter on which they feed and rarely burrow into or ingest much soil (Fig. 1). Typical habitats include forest litter or manure piles, thus they have little direct effect on the structure of mineral soils and are rarely found in tilled fields.

They are usually small, heavily pigmented, reproduce rapidly, and have a short life span. *Endogeic* earthworms burrow extensively belowground and obtain their nutrition by ingesting a mixture of soil and organic matter (Fig. 1). They form extensively branched, subhorizontal networks of burrows in search of food, but most of their activity is in the 10–15 cm upper where organic matter levels are generally highest. Portions of their burrows are often

occluded with their excrement (casts) and they occasionally cast on the soil surface. They are generally medium in size, reproduction rate, and longevity and are lightly pigmented. *Anecic* earthworms are generally larger than the other ecological types, reproduce more slowly, are relatively long-lived, and tend to be pigmented only dorsally. They normally live in permanent or semipermanent burrows that can extend deep into the soil. They feed primarily on decaying surficial organic litter that they frequently pull into their burrows or mix with excrement to form a midden (Fig. 1). The midden blocks the burrow entrance and promotes further decay of the incorporated organic residues. These categories are not absolute, however, as the behavior of many species is intermediate to these groupings and can vary with environmental conditions.^[2]

Fig. 1 Diagrammatic representation of the burrows made by the three ecological groups of earthworms as defined by Bouché.

EFFECTS ON SOIL POROSITY

Because they burrow extensively into mineral soil, endogeic and anecic earthworms can substantially alter soil porosity. Although earthworm burrows usually account for a small fraction of the soil volume, due to their continuity, stability, and relatively large size compared to pores formed by most other mechanisms, these macropores can greatly affect the movement of air, water, and solutes. A number of investigators have demonstrated that burrows made by anecic and endogeic earthworms can effectively conduct water.^[3–5] Because most of their activity is confined to surficial soil horizons, however, endogeic earthworms probably do not directly influence movement deep into the profile.^[6] The fact

that portions of their burrows are often occluded with casts, probably further limits their effectiveness.

On the other hand, anecic earthworms have the potential to influence gas, water, and solute movement throughout the profile. For example, burrows created by *Lumbricus terrestris* L. (a widespread anecic species) are normally single, nearly vertical channels up to 12 mm in diameter and 2.4 m deep.^[2] These burrows can have several entrances directly underneath the midden, but these usually coalesce into a single channel within the upper few centimeters of soil (Fig. 1). Although the midden would seem to inhibit entry of water, field studies conducted on burrows with undisturbed entrances indicate that they can transmit substantial amounts of water, up to 10% of rainfall.^[4,7]

Both burrow types can increase infiltration thereby increasing plant-available water and reducing surface runoff. For instance, when earthworms were eliminated from a pasture, a three-fold reduction in infiltration rate and a two-fold increase in runoff were noted.^[8] In cultivated soils, earthworms can also reduce runoff by disrupting surface crusts that impede infiltration.^[9] The contribution of earthworm burrows to infiltration, however, is dependent on a number of factors. High-intensity rainfall and dry soil can increase flow in earthworm burrows.^[4,5,7] Although it seems logical to assume that earthworms might block flow in their burrows, infiltration rates for burrows with the worm removed are similar to those for occupied burrows.^[10] In fact, occupied burrows are probably more effective in transmitting water than abandoned burrows because they are more likely to maintain near-surface continuity. Theoretically, it should be possible to model the contribution of earthworm burrows and other macropores to infiltration based on their distribution and geometrical properties.^[11] This has proved difficult as not all burrows conduct water and their dimensions are not strongly correlated to their infiltration capacity.^[10,12] Nevertheless, investigators have been successful in linking spatial variability in infiltration patterns on a catchment scale to earthworm populations and macropore distribution.^[13]

In rare circumstances, increased infiltration due to earthworm burrows can have negative consequences. Earthworm burrows can contribute to non-uniform distribution of water during furrow irrigation, loss of water through unlined irrigation ditches,^[6] and leakage of manure storage lagoons.^[14] Anecic earthworms can burrow close to tile lines (Figs. 1 and 2) and may increase losses of injected animal wastes in drainage waters.^[12] Earthworm burrows can also increase leaching of surface-applied agrochemicals, particularly when intense storms occur shortly after application on residue-covered no-till soils.^[4] The potential for this to occur is greatly reduced with time and low-intensity, intervening, rainfalls. Ingestion of herbicide-coated residues by earthworms can also reduce leaching losses.^[15] Once the water enters the burrows, the organic matter-rich linings may further reduce herbicide transport by increasing sorption and degradation.^[3]

Fig. 2 This *L. terrestris* burrow, impregnated with plastic and excavated *in situ*, passed within 2 cm of a buried tile, and had an average infiltration rate of 353 ml min⁻¹.

Furthermore, anecic earthworms can alter carbon distribution in soils by physically moving plant residues into the subsoil, where it may contribute to increased organic carbon sequestration.^[16] There is an unsettled debate as to whether earthworms increase greenhouse gas emissions by enhancing organic matter decomposition or whether there is a net increase in carbon sequestration attributable to stabilizing of organic matter in soil aggregates.^[17,18]

EFFECTS ON AGGREGATION

Although earthworms feed on decaying organic matter and the microorganisms that colonize it, the material ingested by endogeic and anecic species during feeding and burrowing is predominately mineral matter.^[3] This mixture is excreted as casts on the soil surface or belowground, depending on the species of earthworm, location of the food source, and soil bulk density.^[19] The casts usually contain more clay and less sand than the surrounding soil due to selective ingestion with the effect more prominent with endogeic species, which tend to be smaller than anecic earthworms.^[3] Moreover, earthworm casts are usually higher in pH, contain more available nutrients, and have higher levels of microbial activity than the uningested soil.^[1,2]

Freshly excreted casts are initially less water stable than uningested soil because digestive secretions and the peristaltic action of the earthworm gut disrupt many of the existing interparticle bonds. During passage through the earthworm, however, the mineral matter is intimately mixed with ingested organic matter. If casts are allowed to age or dry before being subjected to disruption, their stability can

exceed that of the uningested soil, thereby enhancing formation of a desirable, water-stable, granular, soil structure.^[3]

A number of mechanisms can contribute to the increased stability of earthworm casts with aging or drying. These include chemical or mechanical stabilization by: 1) internal secretions of earthworms; 2) plant fibers incorporated into casts; 3) growth of fungal hyphae; 4) bacterially produced gums; 5) bonding by calcium humate or mucilage; 6) wetting and drying cycles; and 7) age-hardening/thixotropic effects combined with organic bonding.^[3] The mechanisms are not mutually exclusive and the relative contribution of a particular process is probably dependent on a number of factors. For the most part, however, incorporation of organic matter into casts is critical either as bonding agent or as promoter of microbial activity that leads to the production of bonding agents. For this reason a positive correlation between organic carbon content and cast stability is frequently noted. Thus, casts of earthworms that have higher organic matter ingestion rates are more stable than those that ingest more mineral-rich mixtures. Additionally, the distribution of the organic bonding agents is probably more important than the total amount of organic matter within the casts.^[3]

Because freshly deposited casts are initially of low stability, they are subject to dispersion and transport if not protected from raindrop impact or the action of flowing water. Thus, earthworm activity can increase infiltration and reduce runoff while increasing losses of soil and sediment associated nutrients from pastures^[8] and cultivated fields.^[19] Furthermore, foraging and midden building by anecic earthworms can reduce surface residue cover, thus exposing more soil and casts to raindrop impact with negative consequences for soil structure.^[20]

CONCLUSIONS

In general, earthworm activity improves soil structure by increasing macroporosity and enhancing aggregation, which in turn can reduce runoff and sediment loss and provide a better environment for plant growth. Under some circumstances, however, increased infiltration, deposition of casts on the soil surface, and excessive residue removal can have undesirable consequences. For the most part, these problems can be minimized by adopting modified management practices.

Abstract

Soil structure is the combination or arrangement of primary soil particles into secondary units or peds. Soil structure involves the geometric arrangement of particles and interparticle forces that act between them. Soil structure influences how a soil behaves, including how water moves into (infiltration), across (runoff), and through (percolation or drainage) a given soil. This entry discusses pedologic classification of soil structure, general mechanisms of ped formation, and the importance of soil structure for water flow and water quality.

CHARACTERIZATION OF STRUCTURE

Soil peds are characterized by their shape, size, and grade.^[1] The shape of peds is mainly spherical or rectilinear (Fig. 1). Spherical peds comprise *granular* structure. Rectilinear peds are *platy* if their vertical dimension is smaller than the horizontal dimension, *prismatic* if the vertical dimension is larger, or *blocky* if peds have about equal vertical and horizontal dimensions. *Columnar* is a special kind of prismatic structure where ped tops are rounded. Blocky structure can be subdivided into *angular blocky* if peds have sharp edges and corners or *subangular blocky* if edges and corners are rounded.

The size and structure of peds are described by the diameter of granules, the thickness of the plates, the width of prisms, or any dimension of the blocks. Size limits vary from <1 to >100 mm (Table 1).

Structure *grade* is described according to how evident peds appear in a soil exposure and how well they hold together when the soil is handled. Four classes of grade are *structureless*, *weak*, *medium*, and *strong* (Table 1). Structureless soils have no visible structure and are subdivided into two contrasting classes. *Single grain* soils are sandy, and individual particles are not associated with other particles. In *massive* structure, particles are strongly bound to each other but in no recognizable pattern. Soil horizons that have undergone little or no soil formation have massive structure. Also, massive structure is often formed when a fine-textured soil is compacted while wet.

Some soils have compound structure in which large peds break up (part) into smaller peds of different shape. For example, a coarse prismatic structure may break into medium blocky structure (Fig. 2).

FORMATION OF SOIL STRUCTURE

Chemical, biological, and physical processes interact to form soil structure. Soil particles, such as clay, act separately in a *dispersed* system, or they group together to form domains in a *flocculated* system. Domains, in turn, group together to form aggregates, and aggregates to create peds. Flocculated systems form stronger structure than dispersed systems because of particle interaction. If the salt content of a soil (Na^+ , Ca^{2+} , Mg^{2+} , Cl^- , SO_4^{2-} , etc. in soil solution) is high, as in the desert, the soil tends to be flocculated. In most soils, however, salt content is not high enough to cause flocculation. In these soils, the *kind* of exchangeable cation affects flocculation. Sodium ions (Na^+) and to a lesser extent, Mg^{2+} , tend to disperse soils, whereas Ca^{2+} and Al^{3+} tend to flocculate soils. Also, iron and aluminum oxides tend to flocculate soils.

Biological processes are mainly responsible for *granular* structure. Ants and termites secrete organic “glues” that hold particles together. Earthworms ingest soil, mix it with organic compounds, and excrete aggregated soil material. Plants also secrete organic materials that bind soil particles together. These organisms mainly affect surface (A) horizons. Thus, these horizons generally have granular structure.

Blocky, platy, and prismatic structures are formed by intersecting horizontal and vertical fissures or planes of weakness in soils, mainly subsoil horizons. Vertical fissures are created when a soil shrinks. For example, a water puddle often has a layer of fine soil particles at the bottom. When the water evaporates and the fine material dries, it breaks up into polygons separated from each other by cracks. The same process takes place in subsoils.^[2] When soil dries and shrinks, smaller sized peds in the east–west

Fig. 1 Sketches of soil structure shapes: (A) prismatic, (B) columnar, (C) angular blocky, (D) subangular blocky, (E) platy, and (F) granular.

Source: From SSSA.^[3]

and north–south directions are balanced by creation of vertical fissures—the field does not get smaller in area. Soil shrinkage creates some, but fewer, horizontal fissures because soil elevation may actually decrease as soil shrinks. Horizontal fissures may also be caused by freezing and thawing. When soil freezes, liquid water moves to the freezing front where a layer of ice forms and displaces soil material. The freezing front tends to be at about the same horizontal level in the soil. When ice melts, a horizontal fissure is left.

Table 1 Classes of grade and size of soil structure.

Class	Definition			
Grade (strength of development)				
Structureless (0)	No observable structure (massive or single grain)			
Weak (1)	Structure barely observable in place; few peds survive digging			
Moderate (2)	Peds are well formed and evident in place; many peds survive digging			
Strong (3)	Structure distinct in place; most peds survive digging			
Class	Platy (mm)	Prismatic and columnar (mm)	Blocky (mm)	Granular (mm)
Size				
Very fine (VF)	<1	<10	<5	<1
Fine (F)	1–2	10–20	5–10	1–2
Medium (M)	2–5	20–50	10–20	2–5
Coarse (C)	5–10	50–100	20–50	5–10
Very coarse (VC)	>10	>100	>50	>10

Source: From Soil Survey Division Staff.^[1]

Fig. 2 Sketch illustrating compound structure, moderate coarse prismatic structure parting to weak medium angular blocky structure.

Platy structure forms where horizontal fissures predominate, such as near-surface E horizons that undergo many freeze–thaw cycles. *Prismatic* structure forms where vertical fissures predominate, such as in clayey subsoil horizons that dry out due to evapotranspiration. *Blocky* structure forms when horizontal and vertical fissures intersect.

Soil structure is defined according to how individual particles (sand, silt, and clay) are joined together to form peds. Soil scientists, however, describe the end product—how the mass of soil in a profile breaks out into peds. Examples of soil structure descriptions from a published soil survey are “moderate medium granular structure” (A horizon) and “strong very coarse prismatic structure parting to moderate coarse angular blocky” (Bx horizon, fragipan).

Often ped surfaces are coated with clay, and the resulting clay films or skins make ped shape more apparent. Clay is mobilized in near-surface horizons, moves down the soil profile as a slurry, and is immobilized on a ped surface as water soaks into the ped and clay is filtered out on its surface. Chemical changes down the profile, such as a change in pH, may also help clay skin formation. Other mobile constituents (iron or manganese oxides) may also coat ped surfaces.

SIGNIFICANCE OF SOIL STRUCTURE

Characterizing soil structure is based on where soil particles are located, but the significance of soil structure relates to the space where there are no soil particles. Spaces between soil particles are called voids or pores. Pores are often divided into two types—macropores and micropores. Voids between peds are macropores and serve as pathways for roots and rapid water movement. Micropores are smaller pores between particles and aggregates. They hold water between rains for later use by plants.

Flat spaces between adjoining platy, blocky, or prismatic peds are planar voids. The ease with which water moves and roots grow through a planar voids depends on ped

Fig. 3 Sketch illustrating paths of water flow through soils with different soil structure shapes: (A) platy; (B) blocky; and (C) prismatic.

shape (Fig. 3). The route through a platy structure is more tortuous than through a prismatic structure.

Tubular voids, such as root channels and earthworm burrows, are not usually included in the description of structure but are important for water movement and root growth in soils. They act much like planar voids. Often, new roots follow old root channels in which old roots have decayed. Inactive worm channels are especially favorable environments for roots because they are often lined with highly fertile worm castings.

Generally, permeability increases with stronger structural development and smaller peds. Soils with faster permeability are also conducive to better root growth and movement of soil air to roots.

WATER MOVEMENT AND SOIL STRUCTURE

Water moves slowly into and through ped interiors by *matrix flow* and moves rapidly through larger voids as *preferential flow*. Interaction of these two kinds of flow is shown in Fig. 4. In the left part of the diagram, rectangles represent

peds (prisms in this case), and the space between rectangles represents planar voids. The size of the arrow represents the magnitude of rainfall. Thin lines within a prism show matrix flow, and thick lines on the prism surface show preferential flow. Under a gentle rain, the water application, rate 1, all water soaks into (infiltrates) the prism as matrix flow, mainly from the top. With a moderate rain, rate 2, water starts to soak into the prism, but soon the intake rate of the prism is exceeded and preferential or non-matrix flow begins. Then, water also soaks into the side of the prism. Under a hard rain, rate 3, water moves by matrix and preferential flow almost from the beginning of the storm. The same relations are shown in the graph, with the additional information that the infiltration rate into the prism decreases with time. Preferential flow begins when the horizontal line with the arrow crosses the infiltration curve.

SOIL STRUCTURAL STABILITY

Soil structural stability describes the ability of a soil to retain its arrangement of soil and voids when exposed to different stresses and is one of the most important properties that affect a soil's ability to store and transmit water and agrichemicals.^[4] For example, compaction alters soil structure and hydrology by increasing bulk density, breaking down aggregates, decreasing porosity, aeration, and infiltration, and by increasing soil strength and runoff.

SOIL MANAGEMENT FOR WATER FLOW

Runoff, infiltration, and subsequent drainage carry agrichemicals (nutrients and pesticides) to surface and ground waters. Therefore, soil structure affects rates, timing, and amounts of runoff, infiltration, and agrichemical fate and transport. In the subsurface, soil structure influences matrix or preferential flow.^[5]

Agrichemical transport by preferential flow means that water carrying the chemicals travels only through a small portion of the soil volume (not matrix flow).^[6] When infiltration exceeds matrix flow, water and associated agrichemicals overflow into macrochannels causing preferential flow that transmits water and agrichemicals to deeper positions in relatively unsaturated soil materials.^[7]

Although coarse-textured sandy soils generally have little structure, they have good aeration and drainage, promote infiltration, limit runoff, yet lack the capacity to sorb and hold sufficient water and nutrients. They tend to be drought prone and lack fertility. A management practice to improve the structural nature of these soils is to add organic matter, which binds soil particles and promotes water-holding capacity, and can be accomplished by managing residue or addition of amendments such as manures or litter. Structural management of clayey soils is more difficult because potential plasticity and cohesion are high. Increasing aggregation in the surface of fine-textured soils

Fig. 4 Diagram illustrating water flow into and through a soil horizon with prismatic structure. Water application (rainfall) rate 1 is small enough that only matrix flow occurs. Application rate 2 initially produces matrix flow. As the soil wets, the infiltration rate into a prism decreases, application rate exceeds the infiltration rate, and non-matrix flow begins. Application rate 3 is fast enough that non-matrix (preferential) flow begins early and continues throughout the rain storm.

Source: From Bouma, Paetzold, et al.^[8]

will have a dramatic effect on rainfall partitioning into infiltration and runoff and sediment delivery, and subsequent agrichemical fate and transport.

Tillage has favorable and unfavorable effects on soil structure. Moldboard plowing destroys soil structure and aggregation in the Ap horizon, disrupts continuous macropores, increases compaction risk, and retards organic matter build up. One management practice that maintains or enhances soil structure and aggregate stability is reduced (or conservation) tillage. This type of tillage allows for residue management and subsequent organic matter build up. Organic matter is most important in modifying soil structural characteristics and can increase the resistance of the pore network to destructive forces. Because of enhanced soil structure, reduced tillage systems tend to decrease runoff and erosion; increase infiltration, soil water holding capacity, and hydraulic conductivity; and reduce agrichemical losses by runoff.^[9–11] Reduced tillage systems also conserve soil structure including preferential flow pathways (earthworm burrows, root channels, fissures, and/or cracks). Therefore, leaching by preferential flow can be

enhanced by reduced tillage. Transport pathways are grouped into runoff and leaching, each a transporting agent for agrichemicals. Runoff and leaching potentials must be considered when evaluating management practices such as

Structure: Plant Establishment

Douglas L. Karlen

National Laboratory for Agriculture and the Environment, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Ames, Iowa, U.S.A.

Abstract

Soil structure influences plant establishment and plants influence soil structure. Factors involved in the reciprocal relationship (e.g., plant species, soil mineralogy, and human intervention) are summarized to provide an overview of a very dynamic process that can influence food, feed, fiber, energy production, and water and air quality. Soil structure influences plant germination, emergence, root development, growth, development, and yield. How plants affect soil structure and how soil structure affects plants are discussed in this entry.

PLANT EFFECTS ON SOIL STRUCTURE

As a medium for plant growth and development, soil is a three-dimensional, dynamic, naturally occurring blanket on the surface of the earth.^[1] This medium has an inherent (naturally occurring) soil structure that reflects the forces of climate, and living organisms acting on parent material, over time and within a specific topographic or landscape (slope or relief) position.^[2] The naturally occurring soil structure directly affects, and is affected by, the type of plants (e.g., grass, forest, or agricultural crops) and how they are grown. Soils formed under grass (Fig. 1) generally have higher organic matter content and a structure that is conducive for rapid plant growth.^[3] This type of soil structure develops as perennial grasses replace most of their roots and top growth every year. As the litter layer dies, it falls on the soil surface and may be decomposed or mixed into the upper part of the soil by earthworms and other soil organisms.

Grassland soils are generally less acidic than soils that developed under forest. This occurs as grassland soils were generally formed with less annual precipitation than nearby forest soils and as grasses are more effective than trees in recycling nutrients that can be leached. Forest vegetation is more prevalent under a humid (higher precipitation) climate, which also contributes to greater leaching. Trees return organic matter to the soil surface primarily in the form of fallen leaves, twigs, and eventually the entire trunk and its branches.^[3] As the litter layer decomposes, organic acids are formed, thus increasing the weathering of parent materials and subsequent leaching losses. Most organic matter under forest vegetation is concentrated in the litter layer and remains in the upper few inches of the surface or A horizon. Below that relatively shallow zone in forest-derived soils, organic matter is often more eluviated (leached) than under grassland. The net result of these natural processes is that A horizons in

grassland soils (Mollisols) tend to have stronger, more granular structures, and faster infiltration rates than in forest-derived soils (Alfisols), but forest soils are more likely to have deeper profiles and more strongly developed B horizons than grassland soils.

HUMAN IMPACTS ON SOIL STRUCTURE

Human decisions regarding how to use the land for food, feed, and fiber production (i.e., agriculture) have a major impact on soil structure. The effect of choosing to cut native forests (especially by mechanical methods) or till [e.g., plowing, disking, rotary tillage, or even puddling (compaction) for rice] soils rather than to leave them in their natural condition can affect soil structure in both positive and negative ways depending upon the length of time for which the evaluation is being made. The short-term effects are generally positive with regard to crop production, especially on fine-textured soils. Tillage releases essential plant nutrients from plant residues or the soil organic matter and has traditionally provided for weed control. It can also improve the air and water relationships required for plant growth by breaking surface crusts and/or by disrupting dense compacted layers that can restrict plant emergence and growth.

Negative effects of tillage or other aggressive physical disturbances of the soil (i.e., deforestation or over grazing) become more evident when changes are observed over the long term. These impacts include loss of soil organic matter, reductions in total aggregation, declines in the water stability of the remaining aggregates, and decreases in the volume of macropores and biopores (Fig. 2). The long-term negative impacts actually begin immediately after cultivation as soil aggregates are broken apart and the existing structure is weakened or destroyed as the soil is loosened.

Fig. 1 Well-aggregated soil showing plant root growth throughout the profile.

However, the short-term benefits generally mask the long-term effects when observations are primarily focused on plant performance and above ground responses. The negative long-term effects begin to be

Fig. 2 Compacted soil with very little plant root growth throughout the soil profile.

evident after a short period of time as the soil particles gradually consolidate and create a denser soil than in nearby non-cultivated sites. As soil aggregates are broken or dispersed, the fine particles are gradually filtered into the soil pores where they accumulate and block the narrow passageways, thus decreasing porosity and creating even stronger surface crusts. The soil degradation continues as the crusts restrict water infiltration, thus increasing runoff and subsequently soil erosion.

SOIL STRUCTURE EFFECTS ON PLANT GROWTH

Germination is affected by soil structure, as the two primary factors affecting this plant process are soil temperature and water content. Soil temperature is affected by several factors including the angle of the sun's rays, soil color, surface residue or cover, and the depth and time of measurement. The most favorable temperature for seed germination depends on the plant species, but efforts to optimize those conditions, in addition to weed control prior to the development of herbicides, are among the primary reasons that agricultural soils have traditionally been tilled.^[4] The loose and friable soil created by cultivation at the expense of soil structure loses water through evaporation and warms more quickly than more-dense, non-tilled soil. The effects of increased soil temperature and decreased water content are not always positive, especially in coarse-textured soils.^[5] If the seedbed is too dry, germination can be delayed by the lack of water. Under those conditions, it is possible to actually observe plant growth benefits from a slight amount of soil compaction. Also, if the effect of surface tillage on soil temperature below the seed zone is of primary concern, the increased surface porosity following tillage can actually insulate against temperature change deeper into the soil profile. This occurs as the air space created by the tillage operation conducts heat much less efficiently than by either soil particles or water molecules.

Emergence of plant seedlings is affected by soil structure primarily when the surface soil consolidates and forms a crust. This occurs most frequently when soils have been tilled leaving very little surface residue prior to an intense rainfall or surface irrigation event. The thickness and strength of the crusts that can develop will be determined by several factors including the specific type and mineralogy of the soil, the amount of soil organic matter that is present, the stability of the soil aggregates, the intensity with which water strikes the soil-surface, and the air temperature or rate of drying after the wetting event.^[2]

Root development is another plant process that is strongly influenced by soil structure. Under normal conditions, plant roots during early stages of plant development will elongate and extend into the soil 5 to 10 times

Fig. 3 Corn root growth in the surface horizons of a U.S. south-eastern coastal plain soil confined to a mechanically disturbed area created by in-row subsoiling.

deeper than the above ground height. This occurs because after a seedling emerges, the demand for water increases tremendously and the root system must be sufficiently established to meet those demands. If the soil structure does not allow the roots to expand because of inherent fragipans or eluviated soil horizons (Fig. 3) or because of compaction caused by animal hooves or wheel traffic (Fig. 4), plant growth, development, and ultimately yield or productivity will be reduced. The primary requirements for good root development are simply 1) adequate soil oxygen for physiological functioning of the root; 2) sufficient soil water for above and belowground plant needs; 3) soil temperature within the range suited to the plant species; 4) sufficient nutrients and sunlight for the plant to produce and transport carbohydrates (food and hormones) to the root system; and 5) relatively low or insignificant amounts of toxic chemicals, lethal gases, disease organisms, or insect damage.^[6] Keeping these factors in balance is a primary goal associated with agricultural soil management, when evaluated with regard to soil structure and plant emergence.

Fig. 4 Corn root growth in a U.S. mid-western Mollisol confined to the non-wheel track area (right-hand side).

MANAGING SOIL STRUCTURE FOR PLANT ESTABLISHMENT

Soil management research around the world has shown that the use of heavy machinery and frequent disk tillage can compact subsurface horizons in many irrigated soils. The result of such compaction in Morocco was a 12–23% decrease in wheat grain yield and a 9–20% decrease in straw yield.^[7] The decrease was accompanied by a consistent reduction in the number of shoots per unit area and significant changes in both root growth and distribution. In a U.S. study, improving aeration by subsoiling and by avoiding wheel traffic significantly increased sugar beet yield.^[8] This study showed that regardless of the type of tillage used prior to planting, minimizing wheel traffic was one of the most important management decisions that could be made.

Finally, even with reduced-tillage or no-tillage practices, it is important to understand how subtle changes in soil structure can influence plant establishment. A specific example is known as seed furrow or sidewall smearing.^[9] This situation can occur if mechanical planters equipped with double-disk furrow openers are used when soils are too wet. When sidewall smearing occurs, penetration resistance adjacent to and below the seed is increased, pore size is reduced, and air permeability is decreased. One solution is to use different planter attachments, such as a triple coulter, ahead of the double-disk openers. Another would be to delay planting until the soils were slightly drier, but that may also have negative consequences depending upon the crop, length of growing season, and other management factors.

CONCLUSION

Soil structure develops naturally (over time) in response to mineralogy and method of deposition (parent material),

climate, topography, vegetation, and human intervention. Soil structure affects air and water quality through its effect on water entry (runoff), retention (storage), and availability to plants. Soil structure is dynamic. Therefore, understanding how plants influence soil structure and vice versa is critical for sustainable land management.

Structure: Roots

Alvin J.M. Smucker

Department of Crop and Soil Sciences, Michigan State University, East Lansing, Michigan, U.S.A.

Abstract

Soil structure includes a vast array of heterogeneous and separable individual soil aggregates. Soil aggregates are the primary repositories of carbon, water, microbial communities, plant nutrients, and pollutants within the soil profile. Soil aggregates develop and function through complex biological, chemical, and physical interactions with climate, water, and ion activities occurring within and across interfaces of adjacent soil aggregates within the soil profile. Repeated soil wetting and drying cycles develop stronger soil aggregates than the surrounding bulk soil and create smaller internal pores than the surrounding macropores of the bulk soil.

INTRODUCTION

Soil structure includes a vast array of heterogeneous and separable individual soil aggregates. Soil aggregates are the primary repositories of carbon (C), water, microbial communities, plant nutrients, and pollutants within the soil profile. These biophysical polymorph structures, ranging in size from submillimeter to many millimeters across, control the absorption, storage, and losses of most soil constituents. The dynamic properties of soil aggregates are controlled by soil type, anthropogenic inputs, daily changes in the weather, plant roots, and soil animal activities. Separable soil aggregates are formed during the combination of soil minerals, soil organic matter, plant residues, microbes, and other soil biological constituents.^[1] Soil aggregates develop and function through complex biological, chemical, and physical interactions with climate, water, and ion activities occurring within and across interfaces of adjacent soil aggregates within the soil profile. Formation processes of soil aggregates include the cementation of adjacent smaller soil aggregates into larger aggregates^[2] and/or accumulation and cementation of soil minerals, ions, and particulate organic matter onto surfaces of existing aggregates.^[3,4] Repeated soil wetting and drying cycles develop stronger soil aggregates than the surrounding bulk soil and create smaller internal pores than the surrounding macropores of the bulk soil.

PLANT ROOT CONTRIBUTIONS TO SOIL AGGREGATES

Plant species and root architectural contributions to the development of specific soil structural characteristics are well known. Root growth and exudation, fungal associations, and death contribute substantial quantities of C into soil aggregates.^[5] Many of the mechanisms controlling soil aggregation processes and dynamics are unknown.

The research suggests roots opportunistically invade pores between or within soil aggregates depositing soluble C substrates and residues that release C upon decomposition. These root products are energy-rich food sources that stimulate the microbial growth and the production of polysaccharides and other cementing agents that glue soil mineral particles into more stable soil aggregates.^[6–8] In relatively undisturbed soils, root derived C and subsequent decomposition products located within aggregates contribute more to the formation and stabilization of smaller soil aggregates than do plant residues located in the larger pores between aggregates.^[9] Greater numbers of aggregate wetting and drying cycles increase aggregate stability by promoting mineralization of root residues.^[10] Closer proximity of soil minerals, during drying, also increases the bridging strengths of adsorbed organic and inorganic compounds causing greater soil aggregate stabilities.^[11] These and other highly orchestrated plant genetic and environmental interactions govern the majority of these dynamic feed-forward and feed-back root and soil activities.

EVALUATING ROOT–SOIL AGGREGATION INTERACTIONS

Continuous rhizodeposition of C onto soil aggregates is one of the major contributions of crop management to soil structure formation and stability. There seems to be very little information on biogeochemical mechanisms associated with the improvement of C fixed by plants and retained for prolonged periods of time. Sissoko^[8] demonstrated how plant root exudates increase the stability of soil aggregates. Using a 7-day root exudation, incubation, and soil wetting and drying protocol for nine cycles, Sissoko developed soil aggregates containing 70% more microbial biomass and produced 280% more stable aggregates than water-based controls.

Natural Isotopes of C

Evaluating the complexities of C flow from plant roots to their various forms of cementation products within soil aggregates is complicated by the multiple biogeochemical processes of soil C mineralization, the spatial and temporal distributions of various C sources, and the heterogeneity of soil aggregate sizes and stabilities across a vast array of landscapes. Net accumulations of C, originating directly from plant residues or from soil organic matter (SOM), within soil aggregates can be estimated by mass spectrometric evaluations of the natural abundance of ^{13}C in bulk soil. Using soils that produced separate or combined populations of C3 or C4 plants whose metabolisms discriminate in their fixation and accumulation of $^{13}\text{CO}_2$ and $^{12}\text{CO}_2$,^[5] identified SOM and plant root C contributions to the stabilities of multiple soil aggregate sizes. With natural C-13 isotopes, it is possible to identify changes in bulk soil C sources after 6 years of continuous plant growth on the same soil.^[12]

Mechanical Removal of Concentric Layers

Plant-induced changes in soil C accumulations can be identified during shorter time periods by removing and analyzing the C isotope sources in 10–15 mg subsamples from concentric layers of soil aggregates. Santos et al.^[7] identified plant root C accumulations in peeled surface layers of soil aggregates as early as 6 weeks, for corn, using greenhouse containers, or 20 months, for alfalfa, in rotational field studies. Root depositions of ^{13}C and ^{15}N to specific concentric layers within soil aggregates are routinely being reported for aggregates sampled from the rhizosphere soils in surface horizons.^[7,13] Smaller stainless steel soil aggregate erosion (SAE) peeling chambers^[4] that more efficiently produce concentric layers of soil from individual, and smaller aggregates have been developed for identifying C, nitrogen (N), phosphorus (P), pH,^[13–15] and microbial communities^[16] at specific microsites within soil aggregates. These approaches provide numerous opportunities for identifying the rhizodeposition of additional plant compounds from specific C3 and C4 plant species.

Peeled soil layers from aggregates provide information on the deposition rates of both newly deposited labile C and older recalcitrant C within soil aggregates. Kinyangi^[14] demonstrated interdependent and short-term relationships among soil C, N, and P. Using dry combustion analyses of small (10–20 mg) soil samples extracted from concentric layers of soil aggregates, he compared ratios of $^{13}\text{C}/^{12}\text{C}$ soil C, planted to C3 species of *Crotalaria grahamiana* plants whose roots produced a $\delta^{13}\text{C}$ signature of -26.1% , and C4 cultivars of *Zea mays* plants whose roots produced a $\delta^{13}\text{C}$ signature of -10.6% with extractable P from the same peeled layers of aggregates from a Kenyan Oxisol. Using the following equation,

$$\% \text{C from maize} = \frac{[(\delta^{13}\text{C layer}_{\text{final}} - \delta^{13}\text{C layer}_{\text{initial}})]}{(\delta^{13}\text{C crop}_{\text{maize}} - \delta^{13}\text{C layer}_{\text{initial}})}$$

Kinyangi reported that roots of a contemporary maize crop sampled from both field (4 months) and container (5 weeks) studies contributed up to 50% of the measurable soil C in surface layers of Oxisol aggregates, 4–8 mm across. C contents in surface layers of these same soil aggregates declined nearly 23% when fertilizer P was applied to the soil. This study demonstrated a high rate of C deposition by plant roots and transitory C mineralization that controls soil aggregate stability and P availability.

Observations that *Tithonia diversifolia* extracts P from P-deficient Oxisols when soil aggregates are penetrated by very fine roots were confirmed by identifying lower extractable P levels from the centers of peeled soil aggregates that had been penetrated by *Tithonia* roots.^[14] External soil layers of aggregates from P-deficient Oxisols were removed by the SAE method of peeling soil aggregates^[4] and extractable P levels measured. Consequently, greater quantities of soil P can be gleaned from the centers of rigid soil aggregates of P-deficient Oxisols and transferred to food crops via decomposing *Tithonia* plant roots and aboveground residues.^[14]

MICRODENSITOMETRY OF SOIL AGGREGATES

Investigations of interior regions of soil aggregates could lead to a greater understanding of the complex porosities that sequester soil C, microbial communities, and ions. Greater knowledge of water and ion fluxes into and through soil aggregates will lead to knowledge-based opportunities for better managing these complex living centers of the soil. Microdensitometry evaluations of root and soil aggregate interactions are routine analytical options at the GeoSoilEnviro CARS (Consortium for Advanced Radiation Sources) beamline of Sector 13 at the Advanced Photon Source (APS), located within Argonne National Laboratory (ANL) near Chicago, Illinois. Computer algorithms rendered 2-D (Fig. 1) and 3-D images for observations. This image and other synchrotron X-ray images of soil aggregates generate new spatial concepts that expand our knowledge of intra-aggregate and root interfaces. For example, root penetration of these very rigid soil aggregates, 1 mm across, of Kenyan Oxisols permitted root extraction of previously unavailable P from the internal regions of these aggregates.^[14] These types of root-induced macropores (RIMs) also increase macropore connectivities between adjacent soil aggregates, greatly increasing bypass flow through adjacent soil aggregates. Although the APS synchrotron used in these studies is quite large, immobile, and less expensive, new desktop models for routine microtomographic evaluations of porous materials are becoming commercially available. As microdensitometry evaluations of soil aggregates become less expensive, more specific internal porosity comparisons can

Fig. 1 The 2-D image of several electronic slices through microtomographic reconstructions of an undisturbed prairie grass soil aggregate, 1 mm across. Notice the diagonal RIM from top left to bottom right is the remnant of a dehydrated root that contributed root exudates and other plant C substrates to the soil aggregate. This soil aggregate image was produced by K.M. Kemner, B. Lai, and H.-R. Lee at the X-ray beam in Sector 2 of the APS at ANL. Images were recorded by a CCD camera with a pixel unit cell size 7×6 microns.

be made across different soil types and management systems. These evaluations, although somewhat disruptive, when coupled with X-ray diffraction measurements should lead to greater understanding of the biogeochemical mechanisms controlling root uptake of ions as they are associated with the soil minerals at the root–soil interface.

Sub-Irrigation

Norman R. Fausey

Soil Drainage Research Unit, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Columbus, Ohio, U.S.A.

Abstract

Water management has quite a broad scope, including all practices that influence any component of the hydrologic cycle. Within this broad scope are many practices, including things such as cloud seeding to increase precipitation, reservoir management to minimize flood events and to store water for municipal use, the use of plastic mulches to reduce evaporation, and the use of infiltration basins to enhance recharge of groundwater aquifers. Municipal water supply; public safety issues related to flood forecasting, minimization, and urban storm water management; recreational needs; and agricultural production are examples of why water may need to be managed. Agricultural water management practices generally fall into one of following five primary categories: irrigation, drainage, soil erosion control, water supply for animal needs, and waste water disposal. Irrigation involves adding water to assure an adequate supply for crop needs. Irrigation water may be applied on the soil surface or below the soil surface by various methods. One of the methods used to apply water below the soil surface is sub-irrigation.

DEFINITION AND DESCRIPTION OF SUB-IRRIGATION

Sub-irrigation is the practice of adding water to the soil by means of subsurface drains that are also used to drain water from the soil during periods when the soil is too wet. The drains may be open drains (ditches) or closed drains (drainpipes). Water may be supplied from a surface or a subsurface source and is delivered into the subsurface drains and allowed to redistribute within the soil from these subsurface drains. Control structures within the ditches or at the outlet of the closed drains are used to block the water from leaving through the outlet and, thereby, to establish a pressure gradient to cause water to flow from the drains into the soil.

Sub-irrigation is only applicable to areas needing subsurface drainage and having an adequate water supply. These areas typically have high water tables during some times of the year that can be lowered by subsurface drainage. Sub-irrigation depends on being able to reestablish an elevated water table; this requires a substantial amount of water not only to raise the water table, but also to meet the evapotranspiration demand of the crop to maintain the water table at a raised position within the soil.

idea to construct drains to remove excess water from the soil proved successful, the idea of putting water back into the soil through the drains could not have been too far behind. Providing an adequate source of water and a means to move the water against the gravitational gradient would certainly have limited the feasibility prior to the advent of efficient pumping systems. Although not well documented, efforts and progress toward applying sub-irrigation were certainly made, as suggested by an anonymous^[1] quote found in an early publication on drainage, stating: “I want the drains to irrigate with as much as to drain.” An extension bulletin providing guidance for sub-irrigation in Florida was published in 1938,^[2] indicating a recurring early demand for this information in this region. Renfro^[3] summarized and discussed the use of sub-irrigation in the United States up to the mid-1950s. Most of the early applications were on very permeable organic or sandy soils, using open ditches, for high-value crops (vegetables and citrus), and in areas with a readily available water supply, including the Sacramento–San Joaquin Delta in Central California, the Everglades of southern Florida, the San Luis Valley in Colorado, the Flatwoods of the Florida coastal plain, the Cache Valley in northern Utah, the Egin Bench in southern Idaho, and the Great Lakes states.

THE PAST

Agricultural water management using sub-irrigation is not new. It seems reasonable to presume that once the

THE PRESENT

During the past years, agriculture has evolved rapidly. World population pressures, scientific advances, and

changing economic and social values have accelerated a shift in agriculture; diversity has given way to specialization. There are fewer farms and fewer farmers; production per unit of land is greater and is increasing. Risk reduction is a strong driving force in management decisions. Water management has become an important tool for reducing the risk of too much and too little water. This environment has led to a greater awareness of water management options and impacts, and as a result, sub-irrigation has become a topic of increased interest for farmers and researchers.

In 1991, an international conference on sub-irrigation and controlled drainage water management was held in East Lansing, Michigan, U.S.A. The book^[4] that resulted from this conference gives an excellent overview of the status of sub-irrigation around the world. Reports of studies and experience from Canada, China, England, Finland, Italy, the Netherlands, and various locations within the United States are included and illustrate a high level of interest in sub-irrigation.

Sub-irrigation, when properly managed in concert with subsurface drainage, can produce consistently high yields every year regardless of the weather conditions during the growing season. The subsurface drainage function of the system is used to remove excess soil water to assure trafficability for early planting, to lengthen the growing season, and to avoid flooding and lack of oxygen in the root zone, which causes root damage and stunting or death of the plants. The sub-irrigation function of the system is used to avoid deficit water conditions in the root zone, causing stunting and premature senescence of plants. An assured adequate supply of water also allows planning and management for high yields that would not occur when relying on natural rainfall. High yield management involves higher plant populations and more fertilizer application to take full advantage of the available water. With sub-irrigation, yield goals can be raised and still be reached consistently.

Sub-irrigation water management is also beneficial to the environment. An adequate supply of water to meet crop needs encourages maximum growth and, therefore, efficient use of applied nutrients. Nutrients are taken up rather than being left in the soil where they would be subject to being transported to surface water and groundwater as non-point-source pollutants. Sub-irrigation promotes greater production and increases the amount of organic residue returned to the soil. Sustained soil quality and soil health depend on maintaining or increasing the amount of organic matter in the soil. Modern environmental goals also promote the capture and sequestration of carbon in the soil rather than the release of carbon dioxide into the atmosphere. Increasing the soil organic matter content stores more carbon in the soil.

THE FUTURE

Economic and social pressures will likely continue to have a significant impact on agriculture and, consequently, on agricultural water management practices. As society becomes more environmentally aware and sensitive overall, an ethic will emerge for the elimination, or certainly the reduction, of delivery of non-point-source contaminants from agriculture to surface water and groundwater. Some of this has already begun and has resulted in the promotion of uncultivated vegetated corridors along streams designed to slow and filter runoff waters moving to streams. Cost share programs are available in some states to offset the annual loss of production for farmers willing to establish permanent vegetation in these corridors or to assist with the installation of structures to control subsurface drainage discharge to reduce nitrate delivery to streams.

Realistically, it is difficult to control water quality during storm events. Subsurface drainage increases infiltration and decreases surface runoff. The use of sub-irrigation during the summer months would result in less available storage in the soil for rainwater and, therefore, increased runoff, unless the drains are opened quickly and the water table is allowed to fall rapidly ahead of the infiltrating water. Anything that increases runoff encourages the transport of sediments and other pollutants with the runoff water. Water that can be retained in the soil or on the land during storm events will not contribute to runoff and pollutant transport.

Historically, the landscape included more wetland areas where runoff waters were retained or slowed and filtered before reaching streams. Agricultural and cultural development resulted in the loss of many of these wetlands that were also barriers to transportation or breeding grounds for diseases. Removal of the wetlands caused rapid delivery of runoff water to streams resulting in increased flooding and increased transport of sediments and other pollutants to the streams. One way to improve water quality would be to reestablish more wetland areas back into the landscape. Surface runoff and subsurface drainage waters could be directed to these wetlands for treatment and volume reduction before being discharged to streams. Some or all of the water leaving a wetland could be captured/harvested and stored on site in lieu of continuing offsite and downstream. The stored water could meet irrigation or other water supply needs.

Water supply is a critical need for sub-irrigation systems to be feasible and economical. The concept of capture of water during periods when excess water is available and its reuse to meet crop needs during deficit water periods offers an opportunity to make sub-irrigation affordable and practical in many areas. A holistic approach involving the integration of constructed wetlands, water storage facilities, and sub-irrigation of crops offers a unique opportunity to realize

consistent and high crop yields. Such a system will generate more wetland habitat and protect water quality—two of the society's high priority goals. Therefore, the future for sub-irrigation is bright, considering the value to many segments of society to develop and use such integrated systems.

Sub-irrigation as a part of an overall water management plan that protects water quality, increases wetland habitat, and stabilizes crop yields will become the best water management practice.

Abstract

Sugarcane (*Saccharum officinarum*) fields in Southern Brazil have been progressively converted from a burned harvest regime (BH) to a non-burned green mechanized harvest (GH), after which a large amount of crop residue is left on the soil surface. This conversion has resulted in ongoing social, economic, and environmental changes. In this entry, we analyze the aspects of soil physics and chemistry related to this conversion, with special emphasis on carbon dioxide (CO₂) emissions and soil carbon (C) accumulation. We show how small changes in soil C stocks, related to increased soil CO₂ emissions arising from different management options, can impact the C footprint of ethanol. Ethanol is an important option as a replacement for fossil fuels. The results we present and the mechanisms we discuss reveal an optimum land management strategy once the sugarcane areas are converted from a BH to a GH system, and the soil is left covered with sugarcane crop residue. Very different from a bare soil surface scenario, we predict that this is a more appropriate method for sustainable and long-term needs. Here, we maintain that when assessing the long-term effect of sugarcane-based ethanol production, consideration should be given to the long-term effects on the agroecosystem, particularly the soil being the basis for sustainability.

INTRODUCTION

Increased prices and the environmental impact associated with fossil fuel consumption have driven interest in bio-fuels, and concerns regarding food, energy, and the environment have risen considering world production.^[1,2] An estimated 138.8 billion liters of ethanol will be required in 2021 to meet the world's energy demands,^[3] and sugarcane-based ethanol can play an important role in satisfying this need.^[4] Sugarcane is one of the most widely used feedstocks for ethanol production, and Brazil is the largest producer. Production is concentrated in the south-central region and accounts for 90% of national production.^[5] In 2014, sugarcane plantations occupied a total area close to 9.1 million hectares and produced an estimated 28.4 billion liters of ethanol.^[6]

The National Alcohol Program (*Proálcool*) was established in Brazil in 1975 with the purpose of reducing petroleum imports using sugarcane-based ethanol; the environmental benefits were recognized soon after.^[7] This fact, together with the use of hydropower, makes the Brazilian energy matrix far cleaner when compared with most countries where fossil fuels are the main energy source.^[8,9] For example, the widespread introduction of “FlexFuel” vehicles (i.e., designed to run on both gasoline and ethanol) decreased gasoline use in Brazil reducing emissions by 27.5 Tg CO₂eq in 2003.^[10]

Biofuel sustainability has been discussed widely, particularly with regard to preharvest burning during sugarcane agricultural production.^[11,12] There has been much debate on the long-term effects of gaseous emissions from burning on human health.^[13,14] This has resulted in a push from

preharvest burning toward green mechanized harvesting, particularly in São Paulo, even though this management practice has some disadvantages such as using more diesel and fewer workers. Here, we discuss the main aspects associated with the sources and sinks of carbon dioxide (CO₂) emissions under contrasting sugarcane production scenarios, i.e., burned harvest regime (BH) vs. non-burned green mechanized harvest (GH), in Southern Brazil.

Greenhouse Gas (GHG) Balance in Sugarcane Production: Burned vs. Green Harvest

Typically in Brazil, the conversion from a BH to a GH system leaves approximately 10–20 tons of dry matter ha⁻¹ yr⁻¹ on the soil surface after harvest, which represents close to 4.2 and 8.4 tons of carbon (C) ha⁻¹ yr⁻¹, respectively. On the other hand, intensive tillage applied during crop renewal, normally on a five-year planting cycle, can promote high CO₂-C emissions and reduce the potential for long-term soil C sequestration.^[15,16] Reduced tillage and crop rotation during sugarcane renewal are the strategies employed to increase the soil C stock and improve the GHG balance;^[12] a potential GHG mitigation of up to 70.9 Tg CO₂eq has been reported for São Paulo by 2050.^[17]

Change in harvesting methods and leaving crop residues on the soil surface have a huge impact on soil properties: maintaining high soil water content, reducing the soil temperature, reducing erosion, and providing nutrients to the subsequent ratoons.^[18–21] Soil CO₂-C emissions have been studied in sugarcane areas under BH and GH regimes to identify better management practices to reduce emissions

and increase soil C. Some results point to additional emissions of only 250 kg CO₂-C 25 days after tillage as an effect of removing the straw and 1100 kg CO₂-C because of intensive tillage for crop renovation in GH areas.^[16] However, many authors maintain that crop residues should be removed and used as a source of the so-called “second-generation ethanol” or even to generate surplus electricity. There is huge potential for additional power generation in sugarcane straw that can be recovered after harvest. One of the most important Clean Development Mechanism projects applied in Brazil, which uses only sugarcane bagasse after juice extraction, is responsible for 7% of the current electricity generation,^[22] and this is estimated to reach 14% in 2020.^[23]

Approximately, 90% of GHG emissions associated with ethanol production come from the agricultural phase rather than the industrial process.^[5] Thus, when the C footprint of Brazilian ethanol is considered, it is important to take into account the type of management that is applied during sugarcane cultivation (i.e., harvested by burning or non-burning; Fig. 1). De Figueiredo and La Scala Jr^[24] showed that the total CO₂ equivalent emitted in the field during the agricultural production of sugarcane would come mostly from synthetic fertilizers and diesel, and in the case of the BH scenario, the burning of residues accounted for approximately 941 kg CO₂eq ha⁻¹ yr⁻¹. Synthetic nitrogen (N) fertilizers represent approximately 27% of the total GHG balance in GH areas where because of N immobilization by microorganisms, it became necessary to increase their application by 30% during the first years after conversion. Long-term studies reported that small reductions in the amounts of N fertilizer are possible if green mechanized

Fig. 2 Estimation of GHG emission (in kg CO₂eq ha⁻¹ yr⁻¹) associated with sugarcane production, considering 1 ha under burned and green harvest systems: A – subtotal: GHG emissions from synthetic N fertilizer, vinasse, filter cake, residues burning, harvest residues, liming, and diesel; B – C sequestration; C – total GHG balance.

Source: Adapted from De Figueiredo and La Scala Jr^[24] ©2011.

harvesting is adopted for a long period, e.g., more than 15 years.^[25] Furthermore, sugarcane yield is strongly dependent on N fertilization, which is itself responsible for most of the GHG emissions. The work done by De Figueiredo and La Scala Jr^[24] showed subtotals of GHG emissions of 2793 and 3104 kg CO₂eq ha⁻¹ yr⁻¹ in GH and BH, respectively. Moreover, a modest soil C accretion of 320 kg C ha⁻¹ yr⁻¹ (1173 kg CO₂eq ha⁻¹ yr⁻¹) in the GH scenario is important and should certainly be accounted for. This then results in a total GHG balance of 1620 and 3104 kg CO₂eq ha⁻¹ yr⁻¹ in the GH and BH scenarios, respectively (Fig. 2).

Recent publications have also shown the high potential of soil C accumulation in sugarcane fields under green cane management.^[17,26] Cerri et al.^[27] reported that the maintenance of crop residues on the soil surface after harvest could accumulate an average of 1.5 Mg C ha⁻¹ yr⁻¹. However, the simple conversion of sugarcane fields from a BH to a GH system does not guarantee significant increases in soil C stocks over time. Studies have shown that tillage events can result in huge soil CO₂-C emissions during sugarcane field renovation, conducted typically every 5 to 6 years after planting.^[21]

The Effect of Sugarcane Crop Residues on Soil CO₂ Emission

Based on the direct and indirect GHG emission inventories from sugarcane production, our estimations show that when determining the budget in agricultural systems, changes in the soil C stock and its relation to soil CO₂ emissions should be a major consideration. Minor changes in soil C stocks in agricultural areas can impact the total C balance

positively or negatively, with soil C accumulation or loss. This could easily be the highest CO₂ source or, on the other hand, may offset other emissions associated with diesel and synthetic N fertilizer use.

Any management change in agricultural areas results in variations in soil CO₂ emissions. A typical emission of 2 μmol CO₂ m⁻² s⁻¹ would result in 27,372 kg CO₂ ha⁻¹ or 7464 kg CO₂-C ha⁻¹ over a year. Soil CO₂ emission is a large component directly related to soil C transfer to the atmosphere by transference of soil organic matter gains due to crop cycling. It is interesting to notice that just a 10% reduction in the mean magnitude of the soil CO₂ emission, for instance, from 2 to 1.8 μmol CO₂ m⁻² s⁻¹, would reduce soil emissions by approximately 2737 kg CO₂ ha⁻¹ yr⁻¹ (= 746 kg CO₂-C ha⁻¹ yr⁻¹). This is a large component compared with other emission sources, including the soil itself as a possible C sink. As presented in our GHG balance (Fig. 2), savings associated with a 10% reduction in soil CO₂ emission would be equivalent to twice that of what we assumed to be the soil C sequestration once sugarcane areas are converted from BH to GH. This emission reduction of 0.2 μmol CO₂ m⁻² s⁻¹ is something that authors do not pay much attention to, as measuring such a difference between treatments in field experiments, even in agricultural areas, is not easy because of the high temporal and particularly spatial variability of soil CO₂ emissions. Reduction in soil CO₂ emissions, sometimes unnoticed, could save soil C within 1 year and is enough to compensate for other emission sources associated with ethanol production, “zeroing” its C footprint at the end of the production chain.

A set of experiments conducted in the sugarcane areas of Southern Brazil indicate contrasting aspects of the soil CO₂ emission in green vs. burned harvested areas. Panosso et al.^[28] showed a mean soil CO₂ emission in an Eutrustox to be 39% higher in a BH compared with a neighboring GH plot 70 days after harvest (e.g., 2.87 and 2.06 μmol CO₂ m⁻² s⁻¹ for BH and GH, respectively; Fig. 1). Spatial variability models of soil CO₂ emission in both sites indicate a more homogeneous emission pattern from the GH compared with the BH, and CO₂ emission being less influenced by rain, for example. De Figueiredo et al.^[16] in an investigation into the influence of soil management (tillage and liming on an Haplustult) on soil CO₂ emission after sugarcane field renovation showed the important effect of additional soil CO₂-C emission of 253 kg C ha⁻¹ (= 927.7 kg CO₂ ha⁻¹) in a no-till plot. This was induced by the simple removal of sugarcane residues from soil surface, over a period of 3 weeks during which time the soil was left bare, after the replanting of the sugarcane field.

The same effect was observed by Corradi et al.,^[29] whereby the removal of the crop residue from the soil surface resulted in an immediate increase in soil CO₂ emissions. During an experiment carried out over 50 days, it was observed that the emissions from residue-covered soils

Fig. 3 Experimental plots under different crop residues density on soil surface: 0% (D0), 50% (D50), and 100% (D100) of crop residues.

Source: From Mariana Marotti Corradi.

with densities of 3 (D50) and 6 (D100) t ha⁻¹ were less than those from the soil from which the residues were removed (D0; Fig. 3). During the 50 days after the sugarcane residues were removed, CO₂ emissions were higher in D0 than in D100 and D50 (Fig. 4), despite changes in soil temperature and moisture associated with precipitation events. Total emissions, which are defined by the area below the curves (Fig. 4), were as high as 553.6 ± 47.2 g CO₂ m⁻² (mean and standard error) in D0 and as low as 384.7 ± 31.7 g CO₂ m⁻² in D50, which are comparable to D100 total emission. This difference represents an additional emission close to 460.7 kg CO₂-C ha⁻¹ after the complete removal of the sugarcane residue in just 50 days.

Several studies have evaluated the spatial variability of CO₂ emission in areas of bare soil^[30] and those with vegetation.^[31,32] The spatial variation of soil CO₂ emission is

governed mainly by physical, chemical, and biological soil properties, such as soil organic matter content,^[33] microorganism population density in the rhizosphere,^[34] dry bulk soil density,^[30,31] soil pH,^[35] and the available phosphorus.^[36] Furthermore, on a temporal scale, CO₂ emission is controlled by properties that vary over time such as soil moisture,^[37] air-filled soil porosity,^[38] water-filled soil porosity,^[39] soil oxygenation,^[40] and soil temperature.^[37] Schwendenmann et al.^[41] observed spatial relationships between CO₂ emissions, soil C, and phosphorus concentration; temporal variations in the flow of CO₂ were triggered by the soil water content, and the CO₂ flux decreased during the periods when the soil received high precipitation. Brito et al.^[32] also studied soil respiration in sugarcane areas and reported the influence of different topographic positions in the spatial patterns of soil CO₂ emissions.

Soil moisture demonstrates a relation with soil CO₂ emission; increasing it facilitates microbial activity but decreases the oxygen content inside the soil. Linn and Doran^[39] studied the effect of water-filled porosity on soil CO₂ emissions and found that higher emissions occurred when this was approximately 60%. But in an experiment conducted by Corradi et al.,^[29] the temperature and moisture of soil were also affected by the presence (or removal) of sugarcane crop residues, and in general, covered fields had lower soil temperatures and higher soil moisture levels. These parameters do not entirely explain the higher emissions observed in the D0 plot compared to the D100 over the study period.

According to Razafimbelo et al.,^[42] the green mechanized harvest method contributed to soil C accumulation in upper soil layers. In long-term, an increase in the organic C content of 20% and 15% was reported at the 0–5 cm and 0–10 cm layers, respectively. Furthermore, the incorporation of sugarcane crop residues after soil tillage resulted in higher rates of CO₂ emission, since a greater contact between the soil and crop residues, in combination with

Fig. 4 Mean (± half of standard error) of CO₂ emission in the studied days.

Source: Adapted from Corradi, Panosso, et al.^[29] ©2013.

increased aeration and temperature, enhances soil microbial activity.^[15] Assessing the apparent contributions of resident soil C and aboveground crop residue C input to CO₂-C losses, Pes et al.^[43] observed that the crop residue C input was the primary driver of the short-term soil CO₂-C losses during the crop establishment period, and the mineralized resident soil C released by soil tillage gave a limited contribution to increased soil CO₂ emission.

Some Conceptual Aspects on Soil CO₂ Emission

Soil CO₂ emissions can be modeled as they are directly related to the decay of C in soil organic matter, which follows a first-order decay as presented in Eq. 1:

$$\frac{dC_{\text{soil}}}{dt} = -kC_{\text{soil}} \quad (1)$$

where dC_{soil}/dt is the soil C decay in soil organic matter, k is the so-called “decay factor” (time⁻¹), and C_{soil} is the soil C stock (kg m⁻²). The soil CO₂-C emission ($F_{\text{CO}_2-\text{C}}$) should be proportional to soil C decay in organic matter. This is presented in Eq. 2:

$$F_{\text{CO}_2-\text{C}} \propto -\frac{dC_{\text{soil}}(t)}{dt} \quad (2)$$

By relating Eqs. 1 and 2, we derive Eq. 3, which shows that the soil CO₂-C emission (or CO₂ emission) is proportional to the decay factor vs. the C stock in the soil:

$$F_{\text{CO}_2-\text{C}} \propto kC_{\text{soil}} \quad (3)$$

The decay factor (k) is a key issue that should be noted. This factor is related to soil temperature and soil moisture, oxygen content inside the soil, the resilience of the soil organic matter (related to clay content), and how labile the soil organic matter is, this being mostly related to the C/N ratio. Considering Eq. 3, it is theoretically possible to have soils where the C stocks are high, but emissions are low, because of lower values of k in those soils. On the other hand, even soils with low C stocks could have larger CO₂-C emissions due to high k factors. In Eq. 3, it is possible to see that the ratio between $F_{\text{CO}_2-\text{C}}$ and C_{soil} gives an indication of how stable the soil system is in terms of the stability of its soil C. This is an important aspect, particularly when considering the management options available for increasing agricultural production.

With few works published so far, most of the studies relating soil CO₂ emission to soil properties do not pay attention to the soil oxygen content.^[40] This is one of the most important factors influencing microbial activity and hence CO₂ (or CO₂-C) emission. Furthermore, there is growing evidence of the synergistic effect of applying vinasse in the presence of straw on soil GHG emissions. After increasing the amount of straw on the soil surface, the highest emissions (approximately 3000 kg CO₂eq ha⁻¹ yr⁻¹) were reported for ratoon cane treated with vinasse.^[44]

Leaving or removing crop residues on the soil surface seems to interfere with the soil CO₂ emissions so significantly that this could be a strong component in terms of GHG emission.

Here, we emphasize that keeping crop residues on a soil surface could have an important and immediate effect on the soil oxygen content, reducing soil CO₂ emissions and soil organic matter decay. Our results indicate a significant reduction in CO₂ emissions just by leaving sugarcane residues on the soil surface. This is apparently not directly governed by soil moisture. Empirical equations, based on the impact of crop residue removal on soil C stocks, predict that removing residues to produce additional ethanol would have an impact on soil C stocks and GHG emissions in the United States.^[45] This is another indication that the conservation of soil C in agricultural areas should rely on the presence of sugarcane residues on the soil surface, which is an important aspect to be considered in further studies.

CONCLUSION

When considering the soil C budget associated with sugarcane ethanol production in Brazil, it is important to take into account how the soil is managed, with an emphasis on soil C stocks. Small changes in these stocks could significantly increase the C footprint of sugarcane-based ethanol or decrease it close to zero. The soil C budget is a dynamic system in space and time and depends strongly on soil CO₂ emissions, which are shown to be related to the presence or absence of crop residues on the soil surface. When addressing the sustainability of biofuel production, this factor should be taken into account and kept as an option for further studies, as leaving crop residues on soil surface seems to mitigate further emissions associated with agricultural operations.

Sulfate and Sulfide Minerals

Delvin S. Fanning

Abstract

Sulfide and sulfate minerals occur only in small quantities if at all in most soils in humid regions, although certain sulfate minerals, especially gypsum occur in some abundance in soils of arid regions. Where they do occur, however, they can have big effects upon the chemistry of the soils. When exposed to oxidizing conditions either by natural or by human actions, the sulfides oxidize to form sulfuric acid. Unless sufficient acid-neutralizing substances are present, active acid sulfate soils form with many detrimental consequences.

INTRODUCTION

Sulfide and sulfate minerals^[1] are rare to non-existent in most soils of humid regions, but sulfate minerals commonly occur in some soils of arid regions. Where present, these minerals have strong effects on soil chemical properties. It is important to know about the conditions under which they form in soils and the effects they may have on soil properties. Sulfide minerals form in certain anaerobic soils, where there is a source of sulfur (S) as dissolved sulfate in the soil water, e.g., from seawater in tidal marsh soils classified as *Sulfaquents* and *Sulfihemists* by *Soil Taxonomy*.^[2]

Sulfate minerals, in contrast to sulfides, occur in soils that are more aerobic in nature. They may form from sulfides as part of the overall process of sulfuricization.^[1] Generally, they are not present in soils of humid regions because most sulfate minerals readily dissolve and leach from such soils. However, they are present even in humid regions in most active acid sulfate soils, classified as “Sulfaquepts” and “Sulfudepts” by *Soil Taxonomy*.^[2,3] and in some postactive acid sulfate soils. They are more common in soils of subhumid and arid regions, from which gypsum and other relatively soluble sulfates are not readily leached because of limited water supply.

Awareness of S-bearing minerals in soils is important because the oxidation of sulfide minerals and the hydrolysis of certain sulfate minerals form sulfuric acid. When this acid is not sufficiently neutralized by carbonate or other minerals, it results in the formation of acid sulfate soils with pH < 3.5, which can be extremely detrimental to plant growth. The water that emanates from such soils has the

properties of acid mine drainage and can cause fish kills and other severe environmental problems. For more information about acid sulfate soils and associated problems, see other sections of this encyclopedia.

SULFIDES

The S in sulfide minerals occurs as the sulfide anion, S^{2-} , as the disulfide anion, S_2^{2-} , or less commonly as a polysulfide anion.^[1] The sulfide anion is large compared to the S^{6+} cation of the sulfate anion, to which sulfide can be converted by oxidation (Fig. 1). Iron (Fe) sulfide minerals, highly insoluble under strong anaerobic conditions, are the only sulfides known to form and occur to any significant extent in soils. The sulfides of other heavy metals are also insoluble under strongly anaerobic conditions and may occur in very small quantities in some soils.

The Fe disulfide pyrite, FeS_2 , which crystallizes in the cubic crystal system, is the main sulfide mineral that forms and occurs in soils.^[1] Pyrite can occur in soils as a result of sulfidization in tidal environments, where it commonly occurs as framboids.^[1] Alternatively, it can occur in macroscopic crystals, in soils, in mine spoils from the mining of coal, lignite, and ore deposits. In such cases, it may also be present as marcasite, the less stable orthorhombic polymorph of pyrite. The Eh(pe)/pH conditions under which pyrite—the main Fe sulfide mineral that occurs in soils—is stable relative to certain Fe sulfates and goethite, the most stable $FeOOH$ mineral in soils, are shown in Fig. 2.

Monosulfide minerals such as mackinawite, FeS , and polysulfide minerals such as griegite and Fe_3S_4 occur in

Fig. 1 Idealized oxidation of sulfide anion to produce sulfate anion, where the sizes of the atoms and ions are shown in proportion to their expected sizes in nature.

Source: Adapted from Fanning, Rabenhorst, et al.^[1]

small quantities in some soils undergoing sulfidization,^[1] particularly where the levels of Fe in the soil materials occur in excess relative to the amount of S.^[4] In spite of their presence in low quantities, these minerals have a strong black pigmenting effect on soil materials in which they occur, because of their occurrence in dispersed extremely fine particles. Their presence can be detected by the evolution of foul smelling hydrogen sulfide gas from the materials upon the addition of (dilute) hydrochloric acid, whereas no such evolution occurs with the disulfide minerals.

Fig. 2 Idealized Eh(pe)/pH diagram for the Fe-S-O system showing mineral phases that might be expected to be stable under various conditions.

Source: Adapted from Fanning, Rabenhorst, et al.^[1]

SULFATES

Many sulfate minerals are very soluble and behave as salts. However, others such as jarosite and barite are essentially insoluble and can remain in strongly leached soils for many millennia. Fe and aluminum sulfate salts form sulfuric acid upon hydrolysis to form minerals such as goethite, schwertmannite, and jarosite.^[1,5]

Gypsum

Gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, is essentially the only calcium sulfate mineral that occurs extensively in soils. In arid regions, the quantities in some soil horizons may be sufficient for the recognition of the *gypsic* or *petrogypsic* diagnostic horizons and of the *Gypsis* suborder of Aridisols of *Soil Taxonomy*.^[2,3]

Gypsum forms in acid sulfate and other soils upon the reaction of sulfuric acid with calcium carbonate (CaCO_3) and is also a by-product of industrial neutralization of waste sulfuric acid with CaCO_3 .^[1] It is also readily dissolved and reprecipitated, which enables it to move in response to wetting and drying of soils. Sometimes, gypsum is deliberately added to soils, as a calcium source, e.g., to enhance the growth of certain plants (peanuts) or for the reclamation of soils that contain high levels of exchangeable Na.

Jarosite

Jarosite, $\text{KFe}_3(\text{SO}_4)_2(\text{OH})_6$, and natrojarosite, $\text{NaFe}_3(\text{SO}_4)_2(\text{OH})_6$, form in certain active acid sulfate soils. They are distinctive minerals in soils because of their pale yellow color. Jarosites show the present or past occurrence of acid sulfate soil conditions and, in combination with a soil pH measured in water of 3.5 or less, their presence can enable the identification of a “sulfuric horizon” as defined by *Soil Taxonomy*.^[2,3] Jarosite forms in soils under acid sulfate conditions, when the soil pH is sufficiently low and the Eh/pe is sufficiently high (Fig. 2).

Jarosite in soils is highly insoluble as long as the Eh/pe remains sufficiently high for the ferric, Fe^{3+} , form of Fe to be stable. Because of its durability in soils, it may enable the dating of old postactive acid sulfate soils by potassium-argon or $^{40}\text{Ar}/^{39}\text{Ar}$ (argon/argon) methods,^[1] although soil scientists have to employ this technique. Chemical reducing conditions can convert the ferric Fe of jarosite to the ferrous form and make the mineral soluble, like with Fe oxide and oxyhydroxide minerals.

Relatively Soluble Fe Sulfates

Ferrous sulfate minerals, e.g., rozenite, $\text{FeSO}_4 \cdot 4\text{H}_2\text{O}$ (usually white in color), or melanterite, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ (usually aqua blue in color), or other ferrous sulfate minerals depending on humidity conditions^[1] can form in/on soils when ferrous sulfate-rich solutions (see ferrous sulfate

stability field of Fig. 2) are desiccated. These minerals, or the dissolved ions of them, oxidize and hydrolyze readily to form sulfuric acid and Fe (hydr)oxide minerals and are big contributors to the formation of acid drainage waters in some environments.^[1] Relatively soluble ferric sulfate minerals, such as copiapite, $\text{Fe}_{14}\text{O}_3(\text{SO}_4)_{18} \cdot 63\text{H}_2\text{O}$ and coquimbite, $\text{Fe}_2(\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$, form and behave in a similar way, although the Fe is already largely oxidized in these minerals.^[1] Halotrichite, a ferrous aluminum sulfate mineral, $\text{FeAl}_2(\text{SO}_4)_4 \cdot 22\text{H}_2\text{O}$, can also behave in a similar manner.

Sodium and Magnesium Sulfates

A number of sodium (Na), e.g., mirabilite, $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$, and magnesium (Mg), e.g., hexahydrite, $\text{MgSO}_4 \cdot 6\text{H}_2\text{O}$, and mixed Na and Mg, e.g., bloedite, $\text{Na}_2\text{Mg}(\text{SO}_4)_2 \cdot 4\text{H}_2\text{O}$, minerals occur on certain salinized soils such as in North Dakota and Saskatchewan. It is suspected that the S for the formation of these minerals has been released from sulfide minerals deeper in the overall soil-geologic columns upon which these minerals occur.^[1]

Barite

Barite, BaSO_4 , occurs in a few soils.^[1] The origin of this extremely white and very insoluble mineral in soils is poorly understood, although it occurs in some soils that have experienced sulfuricization.^[1] Color pictures and electron micrographs showing the appearance of this mineral in soils are given by Carson et al.^[6]

CONCLUSION

Sulfide and sulfate minerals occur only in small quantities if at all in most soils in humid regions, although certain sulfate minerals, especially gypsum occurs in some abundance in soils of arid regions. Where they do occur, however, they can have big effects upon the chemistry of the soils. Sulfide minerals, especially pyrite, form in tidal marsh soils and in tidal sediments, and they occur in some geologic sediments accumulated under these conditions.

When exposed to oxidizing conditions either by natural or by human actions, e.g., ditching or construction activities, the sulfides oxidize to form sulfuric acid. Unless sufficient acid neutralizing substances are present active acid sulfate soils form with many detrimental consequences as identified elsewhere in this encyclopedia. Sulfate minerals form under oxidizing conditions. Some sulfate minerals are very soluble and are readily leached from soils or are transformed to other minerals. However, certain sulfate minerals, e.g., jarosite and barite, are very insoluble and can remain in soils for long periods of time to attest to acid sulfate soil condition that occurred in the early stages of the formation of some upland soils. The Eh-pe/pH conditions under which certain sulfide and sulfate minerals are stable and are shown in an Eh-pe/pH stability diagram.

Sulfur

Ewald Schnug

Silvia H. Haneklaus

Elke Bloem

Institute for Crop and Soil Science, Julius Kuhn Institute (JKI), Braunschweig, Germany

Abstract

Soil fertility is generally defined as the ability of soils to yield crops and is therefore closely intertwined with plant nutrient cycles. The soil sulfur (S) cycle is driven by biological and physico-chemical processes, which affect flora and fauna. The organic matter pool is an important source and sink for S, though its contribution to the mineral nutrition of high yielding crops has been overestimated in the past. Under temperate conditions, it is the spatiotemporal variation of physico-chemical soil properties, which control the plant-available sulfate-S content in the soil via the access of plant roots to S-rich groundwater or capillary ascending porous water. Therefore, soil methods determining plant-available S status will always only deliver information for that instant ignoring relationships with the plant S status or crop yield. A more promising way to evaluate the S supply is a site-specific S budget, which includes information about geomorphology, texture, climatic data, and crop type and characteristics of the local soil water regime.

INTRODUCTION

The major soil properties and external sulfur sources affecting the amount of plant-available sulfate in the soil are shown in Fig. 1.

For a comprehensive understanding of the relationship between sulfur (S) and soil fertility, it is necessary to identify the main factors and processes controlling the plant-available S pool and to appraise the ecotoxicological significance of S within the context of a limiting factor rather than a pollutant. Detailed reviews about the role of S in agroecosystems already exist^[1–9] and will provide further information, not explicitly mentioned here.

S IN SOILS

The concentration of S in parent materials ranges from 0.026% to 1% S with igneous rocks $\leq$ metamorphic rocks $\leq$ magmatic rocks of upper continental crust $\ll$ limestones $<$ sedimentary rocks (sulfides) $\leq$ shales $<$ sedimentary rocks (sulfates) $\ll$ coal.^[10–12] The typical range of S in agricultural soils of humid and semi-humid regions is 100–500 $\mu\text{g g}^{-1}$ or 0.01–0.05% S. This equals 224–1120 kg ha^{-1} S in the A_h horizon.^[8] The total S content of soils may be as low as 20 $\mu\text{g g}^{-1}$ (0.002%) in highly leached and weathered soils of humid regions or as high as 35,000 $\mu\text{g g}^{-1}$ (3.5%) in marine marsh soils and up to 50,000 $\mu\text{g g}^{-1}$ (5%) in calcareous and saline soils of arid and semiarid regions.^[8] Tropical soils generally contain low amounts of S due to their low organic matter content.

BIOLOGICAL ASPECTS OF S IN SOILS

Most of the S in terrestrial soils is bound in the organic fraction, which amounts normally to more than 95% of the total S content.^[2,8] Organic S in soils is a heterogeneous mixture of soil organisms, partly decomposed plant material, animal, and microbial residues. Little is, however, known about the composition of individual chemical compounds. Many different approaches have been developed to separate soil organic S into major fractions. The following approaches to identify distinct forms and properties of soil organic matter were made: chemical extraction followed by physico-chemical separation into humic acids, fulvic acids, and humins reactivity with reducing agents in order to separate carbon-bonded S (C–S) and sulfate esters (C–O–S) and physical separation of organo-mineral size fractions and molecular weight fractionation.^[13]

Sulfate-S is rapidly bound in the form of sulfate ester, which is regarded as a short-term source for S.^[14] The incorporation of S into high molecular weight fractions such as humic acids prevents the rapid mineralization of S. In litter, S is predominately C–S to the humin fraction to a level of about 89%. The incorporation of organic S into complex organic substances followed by association with clay minerals can lead to the relative isolation of S from decayed soil microorganisms. This process is considered a physical protection of organic S against degradation,^[15] and it results in a decreased availability of S to plants.

Fig. 1 Overview and efficacy of essential impact factors modifying plant-available sulfate in soils.

S Mineralization

In soils, microbial-mediated processes are mainly responsible for S transformations, so that the factors affecting the microbial activity, such as temperature, moisture, pH, and substrate availability will also influence the processes of mineralization, immobilization, oxidation, and reduction. In aerobic agricultural soils, the main factor in these processes is the release of inorganic, plant-available sulfate from organic matter.

Two types of processes are involved in the mineralization of S: biological and biochemical mineralization.^[16] Biological mineralization is considered to be driven by the microbial need for organic C to provide energy, and S released as sulfate is a by-product of the oxidation of C to carbon dioxide. This process is faster the more recently the organic matter was formed.^[17] Biochemical mineralization relies on the release of sulfate from the sulfate-ester pool through enzymatic hydrolysis.

S in the microbial biomass is actively turned over in soils while comprising only ~2–3% of the total soil S. The turnover of soil microbial biomass is fundamental to the incorporation of sulfate-S into soil organic matter, but quantitative measures to assess this are unavailable.

The contribution of mineralization to the S supply of plants is only small,^[2] because mineralization, immobilization, and possible leaching of S occur concurrently.^[14] The amount of S mineralized within the organic S pool in the soil ranges from 0.5% to 3.1% annually.^[2] The contribution of net mineralization accounts on average for 10–30 kg ha⁻¹ yr⁻¹ S^[18] in soils with carbon contents between 1% and 4%. The studies of Eriksen, Murphy, and Schung^[2] and Bloem^[18] reveal that mineralization is an important, however, not cardinal S pool for plants. High yielding crops cannot satisfy their S demand solely by mineralization and atmospheric S depositions.^[7]

Crops and Crop Rotation

Dead plant material contributes to the organic matter pool but the living plant organic matter that partly remains on the field may be regarded as a storage pool for S, too. S offtake and S demand differ depending on the plant species. Sugarcane has a very low S demand with only 0.3 kg S Mg⁻¹ dry matter yield,^[19] cereals about 1.5–2 kg S Mg⁻¹ of grain and 1–3 kg S Mg⁻¹ of straw yield,^[18] soybean between 4.3 and 8.8 kg S Mg⁻¹,^[20,21] mustard about 16 kg S Mg⁻¹,^[22,23] and oilseed rape up to 20 kg S Mg⁻¹.^[24]

The S content of straw highly influences the mineralization of plant residues. Crops, which leave residues with high S contents, may be considered as catch crops for S and are able to reduce S losses from soil by leaching. Cruciferous crops such as oilseed rape show a high S content of the residual straw,^[24,25] which provide a large amount of rapidly decomposable organic material.^[26] In comparison, plants without a secondary metabolism such as cereals leave smaller amounts of S. Only if the S content of, e.g., barley straw is above 0.13% S, the release of S from the mineralization of straw can be expected.^[27] If the value is below 0.13% S, a net immobilization of S takes place because the microbes need more S for the formation of their microbial biomass. This may exacerbate S deficiency of the following crop, e.g., oilseed rape, particularly on light soils, where macroscopic symptoms may become visible even before winter^[25] because of the net immobilization of S. So far there is no evidence that winter crops benefit during their main growth from the previous crop's organic matter residues in plant with high S.

PHYSICO-CHEMICAL ASPECTS OF S IN SOILS

Sulfate has a high mobility in soils and can be delivered from subsoil or shallow groundwater. The water soluble fraction can be leached, adsorbed, immobilized, or taken up by the plant. Availability of sulfate is therefore more a question of transfer between pools in terms of space and time rather than between biological or chemical systems. The insoluble, organic fraction is only slightly leached and is not directly available for plant uptake.

Soil Water Regime

Under temperate conditions, groundwater is often an important S pool, and there are three ways in which groundwater can contribute to the S nutrition of plants. Firstly, there is a direct S input if the groundwater level is only 1–2 m below the surface. This is sufficient to cover the S requirement of most crops, as plants can utilize the sulfate in the groundwater directly by their root system. An average yielding (3 Mg ha⁻¹ seeds) oilseed rape crop covers more than 50% of its S demand by shallow groundwater or soil water.^[24] Secondly, groundwater contains between 5 and 100 mg L⁻¹ sulfate-S which, if used for irrigation, can supply up to 100 kg ha⁻¹ S to the crop.^[18] Thirdly, the capillary rise of groundwater under conditions of a soil moisture deficit in the upper soil layers leads to a S input. The contribution of this process to the S supply of plants depends on the soil texture within the soil profile and climatic conditions. Generally heavier soils show less frequent S deficiency than lighter ones, as they retain more S-rich pore water. This is proven by a significant relationship between groundwater level and clay content and the sulfate-S content of soils.^[18]

Capillary Rise/Leaching

While rainfall water contains only about 2.5 mg S L⁻¹,^[28] the S content of adsorbed soil water varies between 15 and 100 mg S L⁻¹.^[18] Variation of the sulfate content of water in soil pores is caused by temporal changes of the groundwater level, soil depth, and differences in soil texture.^[18] S-rich water in the soil pore ascends in the soil profile if the evapotranspiration rate is higher than the amount of precipitation.

A higher groundwater level below the surface and a high soil moisture deficit at the lower periphery of the root zone will increase the extent of the capillary rise. Giesel et al.^[29] have calculated an average capillary rise of 0.3 mm d⁻¹ on a sandy soil, 3 mm d⁻¹ on a loamy sand, and 5 mm d⁻¹ on a loamy silt with a groundwater level of 1.5 m below the surface. This means that under extreme conditions on sandy soils with a groundwater level >2 m below the surface virtually, no sulfate will be available to the plant due to capillary rise, but on loamy and silty soils, the S supply of crops may be fully satisfied by capillary water, even if the sulfate concentration of the groundwater is low (10 mg L⁻¹ S).^[18] Spring crops particularly benefit from capillary ascending soil water, as their main growth takes place when capillary rise dominates soil water movements.

The rate of leaching of S under temperate conditions depends on soil type, winter precipitation, and the concentration of sulfate-S in the soil water, during the period of leaching.^[18] S losses through leaching are higher over winter due to higher precipitation rates and the lack of plant uptake. As a result, S stored in soils decreases with increasing precipitation, and on sandy, free-draining soils, all sulfate beneath the capillary zone and rooting depth of the crop may be leached before the beginning of the vegetative period^[18] because of the rapid movement of the leachate through the soil and the low adsorption capacities of such soils. Average sulfate leaching depths are 15 cm with 50 mm of precipitation on a loamy soil and 25 cm on a sandy soil, respectively.^[30] Additionally, leaching is higher on fallow than on cropped soils^[31] and is enhanced by S fertilization. Average leaching losses under temperate conditions are in the range of 30–80 kg ha⁻¹ yr⁻¹ S.^[32,33] In addition to vertical water movements in the soil, lateral fluxes can occur particularly in the landscapes with pronounced differences in geomorphology. These fluxes are the major reason for the high spatiotemporal variability of sulfate in soils.

Soil Compaction

Soil compaction and tillage operations causing soil compaction will also decrease the amount of plant-available S because of the reduced soil volume and consequent impact on soil pore space. Consequently, rooting depth and density are decreased so that S-rich capillary water cannot be used.^[34,35] This effect of soil compaction is supported by

the fact that S deficiency regularly becomes visible first in the headland and along tramlines of fields^[7] because it is sulfate-S from the subsoil that mainly contributes to the S nutrition of crops.^[18]

S EMISSIONS

S-containing atmospheric constituents are principally sulfur dioxide (SO₂), SO₄²⁻, SO₃²⁻, hydrogen sulfide, carbonyl sulfide, dimethyl sulfide, carbon disulfide, and methyl mercaptan. Natural S emissions from biogenic sources and from volcanoes add around 60 Tg S yr⁻¹ to the earth's atmosphere with an upward tendency due to the increasing consumption of fossil fuels in South America, Africa, and Asia.^[9]

Before the industrial revolution, atmospheric S depositions were, on an average, below 10 kg S ha⁻¹ yr⁻¹. As a consequence of increased burning of fossil fuels with industrial development from 1890 to 1980, atmospheric S depositions, mainly as SO₂, increased steadily by 0.47 kg S ha⁻¹ yr⁻¹.^[1] In some rural areas of northern Scotland, however, SO₂ depositions were zero or below 2 kg S ha⁻¹ in the 1970s, while the S input in the midlands of England was about 160 kg S ha⁻¹ at the same time.^[36] At its peak, the negative impacts of SO₂ emissions to humans, plants, soils, and buildings were so serious that S became an unpopular nutrient and was called as the "yellow poison."^[37] The political consequences resulted in Clean Air Act in European countries and North America and the desulfurization of emissions led to a drastic decrease of atmospheric S depositions.

Agriculture adapted and coevolved to increasing S loads. Soil acidification caused by high S deposition required higher amounts of liming materials. Increasing S demands of agricultural crops due to higher yield potential as a result of plant-breeding progress and production technology coincided with increased atmospheric S supply. Additionally, the use of S-containing fertilizers went down nearly to zero.^[25] Consequently, the reduction of atmospheric S deposition had a major effect on the productivity of crops. During the 1990s, macroscopic S deficiency became the most widespread nutrient disorder in northern Europe.^[7]

S FERTILIZERS

The worldwide demand of S fertilizers in 2010 is estimated to be about 11.3 million tons of S.^[38] Numerous S fertilizers and secondary raw material fertilizer products are available for either soil or foliar application in sulfate or elemental form.^[39] Arguments for and against the use of individual products depend on local farming conditions. Organic fertilizers such as manure and slurry contain about 1 and 0.5 kg S Mg⁻¹, respectively.^[40] This equals to 0.07 kg S N⁻¹.

AGROECOLOGICAL ASPECTS OF S

Interaction of Agroecosystems with Other Ecosystems

The S input and off-take in agroecosystems may have a strong influence on neighboring ecosystems. S is often in excess in natural systems, despite the low atmospheric S input because the turnover of S is much lower in these than in agricultural systems. Acid subsoils, e.g., under forest vegetation, and peat soils show pH values <5, which are far below the acidity levels of fertile agricultural soils. Large storage capacities for adsorbed sulfate exist on such sites because the pH value of the soil is lower than the zero point of charge, resulting in the hydration of metal oxides and thus a positive surface.^[41] Although adsorbed sulfate plays only a minor role in the direct S nutrition of agricultural crops, it may contribute positively to the S balance of the whole surrounding landscape. Natural vegetation, land without plant production and forests show a positive S balance even when atmospheric inputs are low.^[2] Agricultural crops may benefit from this S pool, if groundwater reservoirs of both ecosystems are connected. This also means, however, that with an increasing share of agricultural farmland in landscapes, the risk of S deficiency overall also increases.

Sustainability

Sustainable agriculture should use soils in such a way that human needs for food or other agricultural goods are realized, and the quality of the environment and the natural resources remain preserved.^[42] The contamination of groundwater with nitrates is a most serious problem. Nitrogen (N) and S are both involved in protein biosynthesis, and a shortage in the S supply of crops also lowers the utilization of applied fertilizer N and thus deteriorates the crop quality. Non-protein N is accumulated in plant parts and besides poor efficiency for N fertilization, and S deficiencies may increase the loss of N from agricultural soils through volatilization and leaching.^[43] On average, each kilogram of S shortage to satisfy the S demand of the crop causes 15 kg of N to be lost to the environment. Such N inputs endanger strongly the stability of natural communities as, e.g., the growth of algae in water bodies.^[44] Correcting S deficiency by fertilization is environmentally safe as sulfate is, in comparison with N, geogenously abundant.

Global Change

Climate is one of the major factors involved in pedogenesis. Soil formation is directly influenced mainly by temperature and water and indirectly via the climate-depending vegetation.^[45] Changes in climate may change soil types, increase erosion, affect element cycles, and increase the release of greenhouse gases. Increased temperature and humidity

accelerate pedogenesis. Thus, global change would allow soils in the northern hemisphere to proceed faster through the individual stages of development and/or degradation associated with their individual soil series.^[46] Higher temperatures accelerate the decomposition of organic materials and thus decrease the organic matter content of soils. At the same time, the net mobilization of S might increase while the organic S pool decreases. This effect is expected to be more pronounced in cultivated than in range soils.^[47] But at the same time under more humid climate conditions organic matter tends to accumulate in soils.^[47] Therefore, an expected adverse effect of global warming on soil organic matter might be at least partially compensated in those areas where this coincides with increasing humidity.^[48] With increasing carbon accumulation, the other growth-limiting elements, such as N, S, and P, may dilute relatively,^[49] which might result in decreased soil fertility.

Plant Health

Owing to the fact that higher anthropogenic S inputs in the past decades enabled plants to adapt to increasing environmental stress, the decline in the S supply within only one decade might have serious consequences for the stability of the ecosystems.^[49] S metabolism provides several efficient mechanisms by which plants are able to tackle abiotic (e.g., xenobiotics and increasing surface ozone levels) and biotic (e.g., pests and diseases) stress, particularly via the glutathione metabolism that again is closely related to the S supply of the plants.^[3] Other mechanisms involved in response to plant pathogens include the production of S-containing compounds in the secondary metabolism of the agriculturally important *Brassica* species, the release of volatile S compounds, the production of S-rich proteins, the localized deposition of elemental S, and the production of phytochelatin, which detoxify heavy metals by forming complexes.^[50,51]

Certain diseases (e.g., light leaf spot in oilseed rape) occur more frequently particularly in areas with low S input in Europe,^[52] and an improved knowledge of the significance of S metabolites in crop resistance to diseases will be beneficial for the improvement of S fertilizer strategies and could therefore minimize the input of pesticides.

ACKNOWLEDGMENT

Abstract

The rhizosphere is a key zone with respect to the mechanisms of soil nutrient dynamics. The effect of plant growth on most soil nutrients in the rhizosphere has been intensively studied. However, only limited data are available for the effect of plant growth on the chemical behavior of sulfur (S) in the rhizosphere. Such information is nevertheless required to assess agronomic and ecological impacts in relation to the local S cycle. In this entry, the state of knowledge about the chemical behavior of S in the rhizosphere is summarized.

INTRODUCTION

Atmospheric sulfur (S) loads are closely linked to soil quality and the S nutrition of plants. An excess of S may have a negative effect on the soil–plant system, e.g., in flooded paddy soils. Here, S will be reduced to hydrogen sulfide, which hinders plant growth. In contrast, atmospheric S deposition cannot satisfy the agronomic demands in the remote areas of China.

CHEMICAL BEHAVIOR OF S IN THE RHIZOSPHERE

Oxidization of S^0 in the Rhizosphere and Non-Rhizosphere

Elemental S (S^0) is often used as a fertilizer to satisfy the S demand of crops. The S^0 needs to be oxidized to SO_4^{2-} before it becomes plant available. The activity of *Thiobacilli* is highly important for the oxidation of S^0 .^[1] Adding *Thiobacilli* together with S^0 to soil yields a significantly faster oxidation rate than the application of S^0 alone.^[2] Heterotrophic microorganisms are also S^0 oxidizers in soils.^[1,3] Grayston and Germida^[4] isolated 273 bacterial phyla and 70 fungal species from the rhizosphere of canola (*Brassica napus*). From these 273 bacterial isolates, 245 (89.7%) oxidized S^0 to thiosulfate or tetrathionate, and 133 (48.7%) oxidized S^0 to SO_4^{2-} . All 70 fungal isolates oxidized S^0 to SO_4^{2-} . Bacterial isolates showed the highest S^0 oxidation rate (Table 1).

A rhizobag culture experiment demonstrated that the oxidation of S^0 in the rhizosphere varied with respect to

soil moisture content and soil type.^[5] The oxidation rate of S^0 was generally lower under waterlogged conditions than under aerobic conditions (Fig. 1). On a paddy soil originating from limestone, the oxidation rate of S^0 was faster in the rhizosphere of rice than in the non-rhizosphere (Fig. 1). However, these differences were not observed on a paddy soil originating from granite. The reason could be related to different contents of plant available S and/or different microbiological species in the two soils.

Soil Microbial Biomass S in the Rhizosphere and Non-Rhizosphere

The microbial biomass S in agricultural soils varies from 5% to 9%.^[6] Despite its small size, the microbial biomass is a highly active fraction that acts as the driving force behind mineralization–immobilization and oxidation–reduction processes. A rhizobag culture experiment demonstrated that the S content of microbial biomass was 6.3 mg S/kg in the non-rhizosphere and 11.8 mg S/kg in the rhizosphere of rice.^[7] The S content of microbial biomass was up to 72% higher in the rhizosphere of rice than in the non-rhizosphere (Fig. 2). In non-vegetated soil samples, the S content of the microbial biomass was usually significantly lower than in vegetated treatments.^[7]

Variations in the Chemical Behavior of S in the Non-Rhizosphere and Rhizosphere

In a rhizobag experiment, it was demonstrated that the distribution of S fractions in a rhizosphere and a non-rhizosphere soil varied with the crop type (Table 2).

Table 1 Number of S⁰-oxidizing bacterial isolates from the rhizosphere and rhizoplane of canola grown in a growth chamber.

Soil	Area of isolation	Total isolates	Number of isolates producing		
			S ₂ O ₃ ²⁻ /S ₄ O ₆ ²⁻	SO ₄ ²⁻	S ₂ O ₃ ²⁻ /S ₄ O ₆ ²⁻ and SO ₄ ²⁻
Haverhill	Rhizosphere	56	49 (87.5%) ^a	25 (44.6%)	25 (44.6%)
	Rhizoplane	43	42 (97.7%)	30 (69.8%)	30 (69.8%)

More ester-bonded S was found in the non-rhizosphere of oilseed rape and rice (Table 2). Hu et al.^[8] observed similar results for oilseed rape, wheat, and radish. The reason could be a higher arylsulfatase activity in the rhizosphere as it is this enzyme that catalyzes the decomposition of sulfate esters.^[9] Han and Yoshida^[10] found that arylsulfatase activity was higher in the rhizosphere than in the non-rhizosphere of rice.

Amino acids, such as cysteine and methionine, are the major components of carbon-bonded S.^[11] S-containing amino acids do not accumulate in free forms because they are rapidly degraded in aerobic soils.^[8] Paul and

Schmidt^[12] reported that cysteine and methionine were slightly greater in a rhizosphere than in a non-rhizosphere soil.^[12] Other experiments revealed no significant differences between the two compartments.^[7,10] These results indicate that carbon-bonded S is of minor importance for the S nutrition of crops compared to ester sulfate.

The amount of residual S (non-reducible S by either hydrogen iodide or Raney nickel) was significantly greater in the rhizosphere than in the non-rhizosphere of oilseed rape, but the opposite results were found for rice (Table 2). Other crops such as wheat and radish also showed higher levels of residual S in the rhizosphere.^[10] Rice had a higher

ability to utilize residual S from the soil, which could be related to its aerenchyma, which transport oxygen from leaves to roots.

The content of soluble SO_4^{2-} -S and adsorbed SO_4^{2-} -S was higher in the rhizosphere than in the non-rhizosphere (Table 2). Enhanced mass flow of SO_4^{2-} -S to the rhizosphere after the mineralization of organic S in the non-rhizosphere is supposedly the reason for this effect. Wind^[13] found that the contents of SO_4^{2-} and $\text{S}_2\text{O}_3^{2-}$ in the rhizosphere of rice were related to rice growth. The same author found more SO_4^{2-} in the rhizosphere (300 $\mu\text{mol/kg}$) of rice than in the non-vegetated (110 $\mu\text{mol/kg}$) treatment (Fig. 3).

ECOLOGICAL EFFECTS OF S TRANSFORMATIONS IN THE RHIZOSPHERE

Grayston and Germida^[4] found that canola leaf size and root and pod dry weight at maturity were improved by inoculation with 7 of 14 S-oxidizing bacteria.^[4] The shoot material had higher iron, S, and magnesium contents after inoculation by 2 of 18 bacterial isolates (Table 3). In the case of three isolates, the treatment had a detrimental effect on growth of the fungal pathogens, *Rhizoctonia solani* AG2-1, *R. solani* AG4, and *Leptosphaeria maculans* "Leroy."^[4]

S in nature occurs in valences from -2 to $+6$.^[14] Many types of organic S compounds exist.^[14,15] Internal cycling

reactions are responsible for maintaining a biologically available S supply through the mineralization of organic substrates and redox transformation of inorganic species.^[14] The speciation of S in natural organic matter could provide a clear understanding of not only biogeochemical transformations of S but also the role of organic S in the complexation of toxic trace metals.^[16] Here, S-containing functional groups in humic substances may play an important role in complex formation with trace metals.^[16]

CONCLUSION

Basic information about the chemistry of S in the rhizosphere is available, but these data refer to specific soil types and crop species. Besides this, the effects of S on nutrient uptake and heavy metal availability are unclear. Crop response to inoculation with S-oxidizing bacteria depends on various factors, such as the isolates and crop species. Further studies are required to understand the ecological significance of S transformations in the rhizosphere.

Sulfur: Nutrition

Silvia H. Haneklaus

Elke Bloem

Ewald Schnug

Institute for Crop and Soil Science, Julius Kuhn Institute (JKI), Braunschweig, Germany

Abstract

Sulfur (S) is a major plant nutrient and its deficiency not only impairs crop productivity and quality but also interferes with environmental demands. Even lesser known is the significance of the S nutritional status for improving the natural resistance of crops against diseases. Under humid conditions, the plant available soil S content is not an appropriate indicator of its availability to crops because of its high spatio-temporal variability even at microscale. In comparison, a comprehensive S balance, which implies meteorological, soil physical, and hydrological parameters, provides a reliable prognosis of the S status. This entry summarizes research information on S nutrition, addressing all agronomic aspects.

INTRODUCTION

Sulfur (S) is normally associated with the acid rain phenomenon and at the peak of industrialization, it became infamous as the yellow poison. Large parts of East Asia suffer in particular from extraordinarily high atmospheric S depositions. In contrast, clean air acts resulted in a drastic decline in S loads and consequently atmospheric depositions declined to zero in rural remote areas of northern Europe.^[1] On soils in these territories, physical and hydrological parameters rather than their soil organic matter (SOM) content influence the size of the plant available sulfate pool in the rhizosphere (see the entry *Sulfur*, p. 2241). Macroscopic symptoms of severe S deficiency are observed routinely on farm lands irrespective of the crop grown (Fig. 1).

Negative impacts on crop productivity and crop quality are severe if not alleviated by timely S fertilization at crop-specific rates. While respective dose-effect relationships are well described in the literature^[2] (Fig. 2), less attention has been paid so far to interactions between S nutritional status and resistance of plants against biotic and abiotic stress. The S-induced resistance (SIR) is one constituent of the complex phenomenon of induced resistance against fungal diseases.^[3] Even more complex seems the cross talk between S nutritional status of crops and their infestation by general and specialist insects.^[4]

An insufficient S supply is directly linked to the nitrogen (N) utilization efficiency, as both nutrients are required in a balanced ratio for amino acid biosynthesis. Under conditions of severe S deficiency, N utilization may be as low as 25%. On an average, each kilogram of S unavailable to

satisfy the demand of the plant leaves 15 kg of N unutilized with the risks to be lost to the environment.

The S supply is of a high ecological importance in the context of green house gases, and it is positively correlated with the release of hydrogen sulfide (H₂S) by plants.^[5] The predicted climate change implies scenarios that might increase the risk of S deficiency by another 11% in the next 70 years. Based on the model calculations of Schnug and Haneklaus^[6], the input of actual climate and crop data show that about 24% of the mean ozone concentration can be degraded by H₂S, provided the S supply is sufficiently high.

Both severe S deficiency and its toxicity may occur in plants, foodstuffs, animal feed, and the human body.^[7] Even more important than detrimental effects of an over-rated S supply on crop parameters is a possibly detrimental effect on animal health. Prominent examples of adverse effects of high S intake on ruminants are polioencephalomalacia, neurological disorder, and hemolytic anaemia.^[8] While deficiency of S in the human diet is rare, Grimble^[9] points out that high intake of L-methionine might increase the homocysteine level in plasma and thus may favor inflammatory centers.

PLANT AVAILABLE S IN SOILS

The variability of sulfate concentrations within one field can be as high as variations between different soil types in diverse climatic zones.^[10] This high spatio-temporal variation of plant available sulfate concentrations under humid conditions is closely related to soil physical and hydrological parameters (see the entry *Sulfur*, p. 2241). The results

Fig. 1 Repeated patterns of small-scale spatial variability of S deficiency in oilseed rape (top; S-fertilized field in lower right corner) and sugar beet (bottom) on a production field in northern Germany.

presented in Fig. 3 illustrate coherences for different soil types, soil water regime, and crop S status. These studies were conducted at a time when S fertilization was only sporadically used.

Severe S deficiency in crops can occur on all soil types and is generally exacerbated by high agronomic yields, soils with a light soil texture, high permeability and low

SOM content, sites poorly connected to capillary ascending groundwater, leaching, reduced root growth and rooting intensity in acid soils, soil compaction, or low soil temperatures. In addition to the spatial variability, rapid temporal changes in soil sulfate are a causal reason for a lack of relationship between soil analytical data and plant S status or crop yield. For predicting the S supply of crops a site-specific S budget, which includes information about geomorphology, texture, climatic data, crop type, and characteristics of the local soil water regime (see Fig. 1), provides reliable data.

S IN PLANTS

The S deficiency in crops induces characteristic macroscopic symptoms, which are comprehensively described by Haneklaus et al.^[1,10] It is commonly evaluated as being highly biocompliant, but there are indications that overrated S fertilization may reduce crop yield, and the adverse effect is related to crop type.^[7]

S AND CROP PRODUCTIVITY

The determination of the total S content in the vegetative plant tissue is a reliable method to assess the S nutritional status of crops. There is no one exclusive critical nutrient value for each crop, as it depends on the growth conditions, the phenological stage of the plant at sampling, the sampled plant part, the determined S species, the targeted yield, and mathematical approach for calculating it.^[10] Data about symptomatological S values, critical nutrient values, and toxicological values have been compiled and statistically computed for different crops for a better appraisal of the S nutritional status of a crop plant.^[10] The relationship between S concentration in plant tissue and yield reflects the physiological patterns in the internal nutrient utilization, which is specific to each plant species and can be best established by boundary lines.^[10]

Fig. 2 Influence of S fertilization on seed and grain yield of winter oilseed rape and winter wheat in relation to the S nutritional status.

Fig. 3 Influence of soil type and soil water regime on the S nutritional status of oilseed rape ($n = 78$) and winter wheat ($n = 82$) on the Isle of Ruegen, Germany, in 1993 (Gw = ground-water, Slw = slack water, Sw = seepage water, and sL = sandy loam).

The BOUNDARY LINE DEVELOPMENT SYSTEM determines the upper boundary line functions and evaluates optimum nutrient values and ranges.^[10]

S AND CROP QUALITY

A sufficient S supply is required for a high quality of bread-making wheat. Its deficiency yields distinctly firmer and less extensible doughs as the elasticity and resistance against extensibility of the dough are related to the concentration of S-containing amino acids and glutathione.

It is the asparagine content of a crop that determines the formation of potentially carcinogenic acrylamide during processing at high temperatures.^[11] S deficiency causes a substantial accumulation of free asparagine in wheat grains and may constitute up to 50% of the total free amino acid pool.^[11] Consequently, there exists a close correlation between free asparagine in the grain and acrylamide formation in heated wheat flour.

The S supply is a key factor influencing the pharmaceutical quality of medicinal plants where S-containing secondary compounds account for the bioactive principal.^[10] Prominent examples are the significant increase of the glucosinolate content in vegetative and generative tissue of Tropaeolaceae (e.g., *Tropaeolum majus*) and the alliin content in Liliaceae (e.g., *Allium cepa*) by S fertilization.

S AND CROP RESISTANCE AGAINST BIOTIC STRESS

Glucosinolates and/or their degradation products, isothiocyanates, are effective against soil-borne fungal diseases, nematodes, and weeds and their targeted use comes under the term biofumigation.^[7]

The term SIR denotes the reinforcement of the natural resistance of plants against fungal pathogens through

triggering the stimulation of metabolic processes involving S by targeted sulfate-based and soil-applied fertilizer strategies. Molecular, physiological, and agronomic aspects of SIR are comprehensively discussed by Haneklaus et al.^[3] The S nutritional level favored the infestation of oilseed rape by specialist insects, but a practical utilization seems not feasible because of and interferences with crop production and crop quality besides the range of agronomic and environmental factors, which control the abundance of beneficial and pest insects.^[4]

CONCLUSION

S nutrition has many facets: minimum factor that impairs crop productivity, crop quality, and plant health; pollutant or indispensable resource to minimizing nitrogen losses to the environment. Substantial progress in developing fertilizer strategies, which address and transcribe an holistic approach of crop production, can be expected since elaborate analytical facilities, all coming under the term “omics” (e.g., ionomics and metabolomics), are available.

Surface Area: Specific

L.A. Graham Aylmore

*Soil Science and Plant Nutrition, University of Western Australia, Nedlands,
Western Australia, Australia*

Abstract

Surface area is an extremely important soil property because a solid can establish contact with another solid, liquid, or a gas, only at its surface. The larger the specific surface area (the surface area per unit mass of material), the larger is the surface energy per unit mass, which is available for both physical and chemical interaction with the surroundings. From the agricultural or environmental point of view, most chemical reactions in soils take place at surfaces within the porous matrix. It is the interaction between the surfaces of the finely divided fraction and the soil water solution, which determines the mechanical or physical properties such as consistency, plasticity, swelling, and shrinking of the soil (i.e., the clay–water interaction). It is on the surfaces of the primary particles that the majority of plant nutrients, heavy metals, and pesticides are held and hence any meaningful study of their retention must, of necessity, be referred back to a unit surface area basis for an understanding of the mechanisms involved.

RELATION WITH PARTICLE SIZE DISTRIBUTION

Surface area depends primarily on the state of subdivision of a particulate material. A system in which the particles are in a fine state of subdivision is termed as a “disperse” system. Large surface per unit mass is a characteristic property of all disperse systems, and the physical and chemical behaviors of such systems depend greatly on the effects, which take place at the interface between two different phases of the system (e.g., between solid and liquid phases). Thus, the clay fraction containing finely divided crystalline and amorphous constituents plays a major role in this regard. For example, 1 g of <2 μm clay possesses approximately 50 times the specific surface area (SSA) of the same quantity of very fine sand and 10 times that of the same quantity of silt; colloidal clay (100 mμ) possesses approximately 20 times the SSA of the same quantity of <2 μm size clay and 1000 times that of the same quantity of very fine sand. It is for this reason that the particles of smallest size in the soil are frequently referred to as the “active fraction.”

DETERMINATION OF SSA

The most universally accepted method for determining the SSA of finely divided porous materials is that of Brunauer, Emmett, and Teller^[1] the BET method. The theoretical description of the process of surface adsorption derived by BET can be written as follows:

$$\frac{p}{v(p_0 - p)} = \frac{1}{v_m c} + \frac{c - 1}{v_m c} \frac{p}{p_0} \quad (1)$$

for adsorption on a free surface, where v is the quantity of gas adsorbed at pressure p , v_m is the amount required to form a monolayer, and c is a constant related to the difference between the heat of adsorption of the first and subsequent layers. The main simplifying assumptions in the derivation of this equation are that the first layer of molecules is adsorbed at a particular energy and that all subsequent layers are adsorbed at an energy equal to that for the condensation of the pure liquid. This is a linear equation and a plot of $p/v(p_0 - p)$ against p/p_0 gives a straight line if the theory is obeyed. The intercept on the vertical axis is $1/v_m c$ and the slope is

$$\frac{c - 1}{v_m c}$$

so that the two constants v_m and c can be obtained from experimental data. In practice, this equation is found to be closely obeyed by most adsorbents over the range as follows:

$$\frac{p}{p_0} = 0.05 - 0.35$$

By measuring v , the volume of gas adsorbed at several pressures within the range over which the equation is applicable, and knowing p_0 , the saturation vapor pressure, we can obtain an estimate of the volume of gas required to form a monolayer over the surface of the soil from the appropriate plot. Knowing the area occupied by one molecule of gas (i.e., molecular area), the surface area of the sorbent material can be accurately estimated.

A number of gases have been utilized in the application of this method to the physical adsorption of gases at low

temperature. When vapor adsorption methods were first developed, Emmett and Brunauer^[2] advocated the use of nitrogen as an adsorbate at 77 K (the boiling point of liquid nitrogen), and this gas has been generally accepted as the most satisfactory. The use of nitrogen as the primary standard has, however, been questioned,^[3,4] there being suggestions that the quadrupole moment of nitrogen can interact with hydroxyl or other polar groups, to varying extents, leading to a change in the cross-sectional area of the adsorbed molecule.

Argon (Ar) adsorption at 77 K or 91 K (the boiling point of liquid oxygen) has been preferred by some workers, as this is a symmetrical non-polar atom, which should be less subject to specific interactions affected by changes in the chemical nature of surfaces. However, argon is less strongly adsorbed than nitrogen, raising some doubts as to whether the BET procedure provides a satisfactory estimate of the monolayer capacity ($c < 50$). Also there are strong suggestions that the effective saturation vapor pressure for argon at 77 K varies between that of solid argon above non-porous materials to that of the supercooled liquid within micropores ($< 20 \text{ \AA}$) and transitional ($20\text{--}200 \text{ \AA}$) pores.^[5,6]

Carbon dioxide adsorption at 196 K has been extensively used in studies on carbon blacks, charcoals, and similar materials.^[7] The surface areas obtained using carbon dioxide on these materials often vastly exceed those obtained by nitrogen adsorption at 77 K, indicating the presence of large volumes of microporous regions inaccessible to the less energetic nitrogen adsorption. Similar effects have been noted with the expanding layer lattice aluminosilicates such as smectite and vermiculite.^[8]

For the measurement of very small surface areas ($< 1 \text{ m}^2/\text{g}$), krypton sorption at 77 K has the advantage of providing a low saturation vapor pressure at the working temperature, and hence a marked reduction in the volume of unadsorbed gas that has to be corrected for in the BET calculation.^[9] Krypton (Kr) adsorption also offers the benefit that its inertness makes it unlikely that it will interact specifically with the solid surface. Because krypton and carbon dioxide sorption at 77 and 196 K, respectively, like that of argon at 77 K, take place below the bulk triple point, the use of these two gases in SSA measurement is likewise subject to some uncertainty in the correct values for saturation vapor pressure to be used in the BET analysis.

The t-Method

Uncertainties in the validity of the BET approach when micro- and transitional pores are present, and in the absolute values of molecular areas and how these will vary with a substrate, which led to the development of alternative methods for comparison of gas adsorption isotherms and surface area determination. Among these, the t-method of Lippens and De Boer^[10] and similar variations^[11,12] have attracted attention as a means of interpreting vapor

adsorption and characterizing the porosity of solid adsorbents. These methods involve the use of “reduced isotherms” in which the volume adsorbed V is plotted against the corresponding statistical thickness (t) of the adsorbed layer on a non-porous reference solid,^[10] or alternatively against some arbitrarily chosen parameter

$$V_s = \frac{V}{V_x}$$

where V_x is the volume adsorbed at^[11]

$$\frac{p}{p_0} = 0.4$$

where adsorption results entirely from monolayer–multilayer formation, straight line plots with slope proportional to the surface area of the sample will be obtained.^[13]

Microporosity and Accessibility of Surfaces

The nitrogen surface areas for the layer lattice aluminosilicate clay materials range from about 10 to 30 m^2/g for the coarser kaolinite minerals through 50–180 m^2/g for the illitic clays. If only the external surface area of the smectites is accessible to the measuring sorbate, as is generally the case for non-polar gases, the surface area involved is frequently of the magnitude of 38 m^2/g (e.g., Wyoming bentonite) to 99 m^2/g (Redhill montmorillonite).^[14] Even these values are, however, influenced by the nature of the dominant exchangeable cation on the clay surface suggesting differences in lamellar packing arrangement.^[8] The use of more strongly sorbed polar molecules such as water, ethylene glycol,^[15] ethylene glycol monoethyl ether (EGME),^[16] and carbon dioxide,^[8,13] and adsorption from solution of cetyl pyridinium bromide (CPB),^[17] methylene blue (MB),^[18] or p-nitrophenol (pNP)^[19,20] provides access to the interlayer surfaces of the smectite clays to varying extents giving substantially higher values (300–800 m^2/g). From chemical analysis and crystallographic parameters, the definitive total SSA can be calculated to be 750 m^2/g .^[21]

The value of the constant c in the BET equation gives a measure of the energy with which the gas molecules are adsorbed by the porous material. For non-polar gas (i.e., electrically neutral) molecules, the presence of the charged cations on the clay surface will have little, if any, effect on the sorption. On the other hand, conducting a similar experiment with polar molecules such as water, the differing effects of different cations upon the adsorption of water are illustrated by the significant differences in sorption energies calculated with different exchangeable cations in the soil. Using this method, Keenan et al.^[22] demonstrated on kaolinitic clay the decreasing effect with increasing size of the monovalent alkali metal ions in the order $\text{Na} > \text{K} > \text{Rb} > \text{Cs}$, as would be expected, the smaller ions having a greater affinity for water of hydration. The obvious

consequence of the presence of cations on the clay surfaces is dramatic variations in the apparent molecular area covered by one molecule as the sorbate clusters around the charged cations.

Similar difficulties are observed with other materials containing micropores, such as the tubular halloysites^[23] and allophanes (SSA ranging from 400 to 900 m²/g),^[24] where the possibility of enhanced sorption of gases through capillary condensation, the physical configuration, and pore shape^[25] make it difficult to interpret sorbed volumes in a meaningful way in terms of surface coverage. Measurement of the SSA of soils is frequently further complicated by the presence of organic matter, which can both significantly reduce the value measured by effectively blocking access of the sorbate to micropores^[20,26,27] or, alternatively, increase it by virtue of its considerable capacity to absorb polar molecules into the structure.^[28,29]

Molecular Areas

Values of molecular area have been determined with fair accuracy for a number of gases, e.g., 0.162 nm² for nitrogen (N₂), 0.138 nm² for Ar, and 0.196 nm² for Kr at 77 K, 0.144 nm² for Ar at 90.1 K, and 0.221 nm² for CO₂ at 195 K. As could be expected, given the tendency of polar molecules to cluster around cation sites, the molecular areas estimated for most such sorbates vary substantially. Derived values include 0.108 nm² for water,^[30] 0.33 nm² for ethylene glycol,^[15] 0.52 nm² for EGME,^[16] 0.54 nm² for CPB (using adsorption from solution),^[17] 1.3 nm² for MB,^[18] and 0.424 nm² for pNP.^[19,20] These derived values are the subject of some controversy.^[21,31]

Negative Adsorption (Co-Ion Exclusion)

In 1947, Schofield^[32] described a method for determining the SSA of clays based on the electrostatic repulsion of anions from the negatively charged clay surface. The volume from which anions (co-ions) are excluded from a negatively charged clay surface in a 1:1 electrolyte solution is given by^[33]

$$V_{\text{ex}} = \frac{2A(1 - e^{\Psi/2})}{K} \quad (2)$$

in which V_{ex} is the volume of exclusion, $2/K$ is the characteristic length in the Debye-Hückel theory of strong electrolytes and is given by $3.04/C^{1/2}$ expressed in Å, C is the concentration, A is the area of the interface, and Ψ is the reduced electrical potential at the Gouy plane associated with the development of the diffuse layer of co-ions. For large electric potentials of the magnitude of -200 mV, the value of $(1 - e^{\Psi/2})$ is 0.98 so the slope of a plot of V_{ex} against $2/K$ would give a good estimate of the surface area. However, potentials of this magnitude are only attained in very dilute solutions. The layer lattice

aluminosilicate clay surfaces are constant charge surfaces for which the Gouy plane potential increases with decrease in concentration. For lithium (Li)-montmorillonite, Quirk and Marcelja^[34] found that the surface potential varied from -36 to -225 mV in lithium chloride solutions ranging from 0.3 to 10^{-4} M. Edwards et al.^[35,36] measured the volume of exclusion for Wyoming bentonite and Fithian illite saturated with the alkali metal cations. The co-ion exclusion plot yielded an SSA of 560 m²/g for Li-montmorillonite and 156 m²/g for Cs-montmorillonite compared with the theoretical hydratable area of some 750 m²/g. For the illite saturated with these cations, the exclusion area varied from 80 to approximately 0 m²/g compared with a nitrogen area of 110 m²/g. The decreasing slope of the co-ion exclusion plots with increasing radius of the ion is associated with the greater accommodation of ions in the Stern layer, thereby reducing the Gouy plane potential and consequently co-ion exclusion. As the basic assumption underlying Schofield's equation that the surface charge is large is not met, co-ion exclusion is clearly not appropriate for measuring the surface area of clays, although it is incorrectly cited in the literature.

CONCLUSION

The surface area available to any given sorbate is determined essentially by surface reactivity and geometrical considerations. Hence their use should be governed by the intent and purpose of the surface area measurement. Despite the reservations with respect to saturation vapor pressures, application of the BET theory to the adsorption of N₂, Ar, and Kr gases at low temperatures provides the standard procedures for the measurement of the external surface areas of finely divided materials using automated systems. More realistic measurement of the surface areas available in hydrated or solvated systems, where interlayer surfaces are accessible, can be obtained by the use of more strongly adsorbed polar molecules such as water, EG, EGME, or CPB. However, the affinity of charged molecules for cations, uncertainty in their surface orientation, and extent of surface coverage severely limit confidence in the accuracy of these methods. For comparative purposes, the use of water vapor sorption at

$$\frac{p}{p_0} = 0.19$$

on homoionic soils probably provides the most useful method of assessing the relative surface areas of soils.

Surface Management

Kwong Yin Chan

Organic Wastes Recycling Unit, New South Wales Department of Primary Industries, Richmond, New South Wales, Australia

Abstract

Surface soil controls a number of processes, namely gaseous exchanges, hydrology, carbon, and nutrient cycling, all vital for the functioning of the soil. These are controlled by the structure of the surface soil. In agriculture, management of surface soil structure requires an integrated approach including physical and mechanical, chemical, and biological methods.

INTRODUCTION

Surface soil, the uppermost part of the soil profile ordinarily moved in tillage (i.e., the plow layer, Ap horizon), or its equivalent in uncultivated soils, ranges in depth from 7 to 25 cm.^[1] This is the part of the soil profile: 1) that is in intimate contact with the atmosphere; 2) that regulates and partitions water in the environment; 3) where most of plant roots and soil organic carbon are concentrated; and 4) where most of the biological and nutrient-cycling activities take place. All these processes, which are vital to the functioning of the soil, are directly controlled by the structure of the surface soil. At the same time, surface soil is also most affected by human activities associated with agriculture, mining, and urbanization. Clearing land of native vegetation for agricultural development and inappropriate management practices, both of which affect mostly the surface soil structure, is the causes of worldwide land degradation problems, namely, compaction, erosion, desertification, siltation, dust storms, and eutrophication.^[2,3]

IDEAL SOIL SURFACE STRUCTURAL CONDITIONS

Functionally, the surface soil should have a range of pore sizes suitable for transmission as well as storage, free drainage, and root proliferation.^[4] A system of classifying structural quality of surface soil based on these factors has been defined in [Table 1](#).^[5] Determined mainly by soil bulk density, this system is influenced by texture only for the extreme classes, namely, clays and loamy sands.

Besides having a suitable porosity (structural form), surface soil structure should also be assessed in terms of stability and resilience.^[6] Stability is a measure of the ability to resist structural breakdown when subjected to stresses, while resilience is a measure of the ability of the soil to recover its structural form after disturbance. Both stability

and resilience are, to a varying extent, dependent on soil organic carbon levels.^[6]

DIFFERENT MANAGEMENT METHODS

Many management practices in agriculture and other land use affect soil structure, either directly or indirectly, because of their effects on the factors and processes involved in soil structure formation.^[3,4,6] While soil surface structural degradation problems (such as compaction, crusting, surface sealing, and hardsetting) are often caused by poor management practices such as excessive and inappropriate tillage, bare fallowing, and stubble burning/removal, management practices that are effective in improving/ameliorating soil surface structure also exist. These practices are described under the following categories:

Mechanical and Physical Methods

Tillage

Tillage is traditionally the most common practice used to modify soil surface structure. It can have large impacts, beneficial as well as adverse, on surface soil structural condition. Appropriately used, it is useful in providing suitable seedbeds, alleviating physical impedance (e.g., crusts), and managing crop residue.

On the other hand, inappropriate and excessive tillage has been the cause of widespread land degradation problems in many parts of the world (e.g., the dust bowls in the United States during the 1930s).^[3,7]

The worldwide trend is toward reducing the number of tillage operations (reduced tillage) and even eliminating them altogether in cropping (zero tillage), as advocated by the conservation tillage movement.^[8,9] Significant reduction in soil erosion and improvements in water infiltration and surface soil aggregation have been reported

Table 1 A system for classification of surface soil structural quality.

Class	Air-filled porosity at FC ^a (% v/v)	Water-holding capacity (mm/m)
Very good	>15%	>200
Good	10–15%	150–200
Moderate	5–10%	100–150
Poor	<5%	<100

^aFC = soil water potential (–5 KPa).Source: From Hall & Reeve.^[5]

under reduced/zero tillage systems when compared with conventional tillage systems.^[3,8,9] There is a recognition of the need to rationalize tillage so as to maximize its benefits and minimize its adverse effects. Adopting controlled traffic systems of farming, in which the wheel tracks of all operations are confined to fixed paths, prevents recompaction of soil by traffic outside the selected paths. As the field is divided into cropping and traffic zones, the undesirable effects of tillage on soil structure in the cropping zones can be avoided. Careful consideration of the type of tillage implement, as well as the frequency of tillage, is also important in crop-residue management (amount and orientation), which plays a vital role in wind- and water-erosion control.^[8]

Natural processes

These refer to the natural processes of wetting and drying and freezing and thawing, which can influence soil surface structure.^[10] These processes can be influenced to improve surface soil structure. Many traditional farming practices use these natural processes to manage soil structure. For instance, one aim of autumn cultivation by European farmers is to put the soil into a condition where it will gain maximum benefits from the freezing and thawing of frost action by exposing the maximum clod surface at a suitable moisture content to produce frost tilth.^[11] Combined actions of wetting and drying are responsible for mellowing due to production of incipient cracks.^[10] Both processes of soil restructuring work better for clay soils than for sandy soils.

Chemical Methods

These refer to the application of natural or synthetic chemicals to improve soil structure. Generally, they act either by overcoming the chemical causes of instability (e.g., dispersion) or as stabilizing agents. For example, the application of gypsum to sodic soils can stop dispersion, improve physical condition of the surface soil, and increase crop yield.^[12]

Soil conditioners in forms of synthetic organic polymers [e.g., polyvinyl alcohol (PVA) and polyacrylamide (PAM)]

can stabilize soil structure and improve soil physical conditions.^[4] Hitherto, their uses have been restricted to intensive horticulture because of the high costs involved. However, with the availability of new water-soluble polymers, the application rate, and, therefore, the costs involved have been greatly reduced.^[13]

Biological Methods

These are practices that involve using living organisms or their products for the improvement/maintenance of surface soil structure. The benefits of a pasture phase (ley) as part of the crop production system in maintaining favorable soil physical conditions have long been recognized.^[4,14] The pasture phase improves soil structure because of the activities of the denser root network and higher organic carbon inputs when compared with the crops.^[3,6,15] The pasture roots create new pores as well as enlarge and stabilize existing ones. The increase in structural stability results from a combination of the direct effects of enmeshing and entanglement, as well as the indirect effects of associated microbial activities and the release of binding material by the roots. Improvement in soil structural stability due to increases in soil organic carbon under increasing duration of pasture has been documented (Fig. 1).^[15] Retention of crop residue (straw) provides surface protection against raindrop impact

Fig. 1 The relationship between water-stable aggregation and organic carbon levels under different crop/pasture rotation (P = pasture; W = wheat; F = fallow).

Source: From Tisdall & Oades.^[15]

and wind in the short term and assists in maintaining/increasing the soil organic carbon levels, and hence the soil structural stability, in the long term. Application of organic matter as manure is a time-honored practice for maintaining/improving surface soil structure.

Introduction of soil fauna

Activities of many of the soil fauna, such as earthworms, ants, and termites, can modify soil structure. Earthworms can improve soil structure by creating burrows (macropores) and promoting surface aggregation because of their casting activities.^[16,17] Significant improvements in surface soil structure and hence soil physical properties, such as increased water infiltration, porosity, and water-holding capacity, have been demonstrated as a consequence of introducing certain earthworm species to new locations.^[17]

IMPORTANCE OF AN INTEGRATED APPROACH

While many of the aforementioned methods, when implemented separately, have beneficial effects on soil structure and therefore on soil physical properties (Table 2), an integrated approach is required in practice. For effective improvement/maintenance of surface soil structure, these methods complement each other and usually more than one method is needed. For instance, in conservation

tillage both reduction in tillage intensity and retention of crop residue are employed. Chemical/mechanical methods alone are merely short-term solutions that are ineffective and may even result in adverse effects, in the longer term. Excessively tilling a soil that is already low in stability (because of low soil organic matter level) will only make the soil more tillage-dependent, vulnerable to complete structural collapse on wetting, and prone to crop failure.^[19] However, under certain circumstances they can serve as a starting point for overcoming the initial/inherent limiting soil structural conditions (e.g., the use of gypsum to overcome clay dispersion). Macropores, which are important components of the surface soil structure, can be effectively created/maintained only by biological agents (e.g., plant roots, earthworms, and termites) as biopores.^[10] This highlights the importance of biological methods as a part of the long-term soil surface management package.

CONCLUSION

Surface soil controls a number of processes, namely gaseous exchanges, hydrology, carbon, and nutrient cycling, all vital for the functioning of the soil and are controlled by the structure of the surface soil. In agriculture, management of surface soil structure requires an integrated approach including physical and mechanical, chemical, and biological methods.

Surface Water: Nitrogen Enrichment

Tim P. Burt

Penny E. Widdison

Department of Geography, University of Durham, Durham, U.K.

Abstract

Nitrogen (N) is essential for plant growth and comprises nearly 79% of the earth's atmosphere in the form of N_2 gas. In order for N to be used for plant growth, it must be “fixed” in the form of ammonium or nitrate. In the terrestrial N cycle, microbes break down organic matter to produce much of the available N in soils. Nitrate is completely soluble in water and it is not adsorbed to clay particles; therefore, it is vulnerable to being leached out of the soil by percolating rainfall or irrigation water.

INTRODUCTION

Generally, the movement of nitrogen (N) can be described in three ways: 1) upward, crop uptake, and gaseous loss; 2) downward, as leaching to groundwater; and 3) lateral, via surface and subsurface flow to surface waters. The N cycle under arable soils is shown in Fig. 1.

NO₃ LEVELS IN SURFACE WATERS

The natural water quality of a river will be determined primarily by the catchment soil type and underlying geology to which water, falling on the catchment as rain, is exposed as it drains to the river. Climate provides an important context for N cycling by controlling the propensity for carbon and N to be stored within the catchment; thus, in the United Kingdom, upland soils tend to conserve organic matter as peat, whereas organic matter tends to decompose much more readily in lowland soils. Deviations from this baseline water quality are generally caused by the influence of human activities through point and diffuse pollution sources. Up to 40% of total N reaches the aquatic system through direct surface runoff or subsurface flow.^[1] N delivery to surface waters is further controlled by: 1) soil structure and type; 2) rainfall; 3) the amount of NO₃ supplied by fertilizers; and 4) plant cover and root activity.^[2]

In pristine river systems, the average level of NO₃ is about 0.1 mg L⁻¹ as N (mg L⁻¹ N). However, in Western Europe, high atmospheric N deposition results in N levels of relatively unpolluted rivers to range from 0.1 to 0.5 mg L⁻¹.^[3] NO₃ concentrations in European rivers have been rising (Fig. 2) and “No progress has been made in reducing the concentration of NO₃ in Europe's rivers.”^[4] High rates of N input to rivers and coastal waters are not

confined to Europe. In an average year, the Mississippi River discharges 1.57 million metric tons of N into the Gulf of Mexico.^[5] About 7 million metric tons of N in commercial fertilizers are applied annually in the basin leading to NO₃ concentrations in agricultural drains of 20–40 mg L⁻¹ or more.^[5] In the United States, in 1998, more than one-third of all river miles, lakes (excluding the Great Lakes), and estuaries did not support the uses for which they were designated under the Clean Water Act.^[6] Table 1 illustrates N inputs to rivers and coasts in areas of America, Africa, and Asia.

It is widely acknowledged that agriculture is the main source of N pollution in surface waters and groundwater in rural areas of Western Europe and the United States.^[2,7,8] The U.K. House of Lords' report *Nitrate in Water*^[9] commented on the conflicts that can arise when the use of land for farming comes into conflict with the use of land for water supply. Concern initially focused on alleged links between high NO₃ concentrations in drinking water and two health problems in humans: the “blue-baby” syndrome methemoglobinemia and gastric cancer. There are also concerns for environmental degradation. Nutrient enrichment in water bodies encourages the growth of aquatic plants (see Fig. 3). Reed beds and other marginal plants may be attractive on a small scale, but when these and, particularly, underwater plant growth are excessive, this can cause a narrowing of waterways and become a nuisance to recreational users of rivers and lakes. Furthermore, eutrophication (a group of effects caused by nutrient enrichment of water bodies) can adversely affect the aquatic ecosystem. An algal bloom may cut out light to the subsurface, and when it dies back, decomposition uses the oxygen supply needed by other species. Some algae are toxic to fish, while others, e.g., cyanobacterial species, are toxic to mammals including domestic pets.^[10]

Fig. 1 The N cycle under arable soils.
Source: From Burt, Heathwaite, et al.^[2]

Studies in Asia have demonstrated the link between increasing use of fertilizers and increasing incidence of algal blooms. Table 2 illustrates rates of fertilizer application for selected Asian countries. In some Chinese provinces, fertilizer application is greater than 400 kg ha⁻¹. This is usually applied as a single application, and with crop utilization efficiency as little as 30–40%, a high proportion is lost to rivers, lakes, and coastal waters.^[11] The environmental impact at the

regional level has led to a rise in the incidence of red tides (algal blooms). During the 1960s, less than 10 red tides per year were recorded, but in the late 1990s over 300 per year were recorded.^[11]

The popular misconception that the NO₃ problem is caused by farmers applying too much NO₃ fertilizer is too simplistic. Nevertheless, there is little doubt that the high concentrations of NO₃ in fresh waters noted have mainly resulted from runoff from agricultural land and

that the progressive intensification of agricultural practices, with increasing reliance on the use of nitrogenous fertilizer, has contributed significantly to this problem. Since 1945, agriculture in the industrialized world has become much more intensive. Fields are ploughed more frequently; more land is devoted to arable crops, most of which demand large amounts of fertilizer; grassland too receives large applications of fertilizer to ensure a high quality silage for winter feed; stocking densities in general are higher, leading to increased inputs of manure on grassland and problems of disposal of stored slurry; cattle often have direct access to water courses resulting in soil and bank erosion and direct contamination from animal waste; many low-lying fields are underdrained, encouraging more productive use of the land and speeding the transport of leached NO_3 to surface water courses. It is true that lowland rivers close to

urban areas receive larger quantities of N from sewage effluent, but budgeting studies confirm that agriculture is the main source of NO_3 in river water.^[11,13]

Betton et al.^[14] have mapped NO_3 concentrations for mainland Britain. A marked northwest to southeast gradient is evident, reflecting relief, climatic conditions, and agricultural activity. Upland areas in the north and west are usually characterized by NO_3 concentrations below $1 \text{ mg NO}_3\text{-N L}^{-1}$. This reflects the high rainfall and low temperatures of such areas: upland soils tend to conserve organic matter and mineralization rates are low. In contrast, a decreasing ratio of runoff to rainfall and an increasing intensity of agricultural land use toward the south and east of Britain result in higher mean concentrations of NO_3 in river water. Many of the lowland rivers are characterized by concentrations above $5 \text{ mg NO}_3\text{-N L}^{-1}$; in East Anglia and parts of the Thames basin, mean NO_3 concentrations in rivers are close to the E.C. limit of $11.3 \text{ mg NO}_3\text{-N L}^{-1}$, a level exceeded in some spring waters especially in the Jurassic limestones of the Cotswolds and Lincolnshire Wolds.^[15]

The changing pattern of lowland agriculture since 1945 is reflected in long-term records of NO_3 for surface and ground waters.^[15] For both large and small rivers, there has been a relatively steady upward trend in NO_3 concentrations,

Fig. 3 Choked watercourse, River Skerne, County Durham, August 2002.

Source: From Courtesy of P. Widdison.

often of the order of 0.1–0.2 mg NO₃–N L⁻¹. Analyses for relatively short time series of just a few years (e.g., Betton and Webb^[14] have shown that the upward trend may be interrupted, either because of climatic variability (drier years are associated with lower NO₃ concentrations) or because of land use change. Nevertheless, statistical analysis of long time series shows that the main effect is a steady increase in NO₃ levels over time that is independent of climate.^[15] If trends continue, the mean NO₃ concentration of many rivers in Europe will soon be above the E.C. limit; in many cases, this level is already exceeded during the winter when NO₃ concentrations reach their maximum. In catchments where groundwater is the dominant discharge source, this long-term trend may be prolonged as it may take years for NO₃ to percolate down to the saturated zone. In such basins, NO₃ pollution may remain a problem for decades to come. A number of options have been considered as a means of halting the upward trend.

LAND USE CONTROLS TO REDUCE N ENRICHMENT TO SURFACE WATERS

Trends in water management in Europe include moves toward catchment-level management, improved intersectoral coordination and cooperation, and frameworks facilitating stakeholder participation. This approach is developed by the European Union in its Water Framework Directive, which sets targets for good ecological status for all types of surface water bodies and good quantitative status for groundwater.^[3] More localized schemes, like the U.K. Nitrate Vulnerable Zones, involve greater restrictions on farming practice, such as restricting the amount and timing of organic and inorganic fertilizer application. The EU Common Agricultural Policy is to change the way payments are made to farmers. Single-farm payments will encourage farming in a more environment friendly way. Financial payments may be available to farmers for loss of income or for changing farming practice such as improving slurry storage and fencing off watercourses to restrict livestock access.^[2] Much interest focuses on the use of riparian land as NO₃ buffer zones.^[16]

The terrestrial–aquatic ecotone (boundary zone) occupies the zone between the hillslope and the river channel, usually coinciding with the floodplain. Given their position, nearstream ecotones can potentially function as natural sinks for sediment and nutrients emanating from farmland. Observed denitrification rates in floodplain sediments may be sufficient to remove all NO₃ from groundwater flowing under a riparian woodland, with a floodplain width of 30 m. Saturated, anoxic soils, rich in carbon, are exposed to NO₃-rich groundwater. Rates of denitrification are high within this zone because the nutrients required by denitrifying bacteria are abundant.

Wetlands and wet meadows (defined as areas where the water table is at or above land surface for long enough each year to promote the formation of hydric soils and support the growth of aquatic vegetation) also have potential as N sinks.^[17] High production rates by wetland vegetation result in an abundance of carbon providing an organic substrate for bacterial processes. Wetland plants transport oxygen into anaerobic sediments, which can enhance denitrification leading to losses of N as N₂O or N₂ from wetland sediments.

The type of vegetation found on the floodplain controlling the efficiency of NO₃ absorption is the subject of much debate (see, e.g., Haycock et al.).^[16] Several studies have argued the presence of trees is crucial; yet others state the role of surface vegetation is secondary to the presence of saturated conditions together with carbon-rich sediment. Denitrifying bacteria operate best at the junction of anaerobic/aerobic zones where both carbon and NO₃ are abundant. It is clear that NO₃ losses may be reduced by creating a nutrient-retention zone between the farmland and the river. Given that many floodplains around the world are part of an intensive agricultural system, creating permanently vegetated buffer strips between field and water courses is an idea that should be actively promoted. However, buffer strips will only be successful nutrient sinks if they are managed in an appropriate way. Underlying artificial drainage should be broken or blocked up to prevent a direct route to the watercourse for solutes, and grassland strips need maintenance to prevent them becoming choked with sediment and losing their sediment retention potential.

Solving the problem of nutrient enrichment of surface waters cannot be seen in the short term. Long-term land use change is needed. Taking farm land immediately adjacent to water courses out of production is one option that could go some way to allow modern agriculture and water supply to coexist in the same basin.

Surface Water: Pollution by Nitrogen Fertilizers

Gregory McIsaac

Natural Resources and Environmental Sciences, University of Illinois at Urbana-Champaign, Urbana, Illinois, U.S.A.

Abstract

The use of industrially manufactured nitrogen (N) fertilizers increased rapidly in developed countries between 1960 and 1980. This facilitated a large increase in the production of feed and food grains (maize, wheat, and rice) per unit of cultivated land, but in some regions it also contributed to enrichment of surface and groundwater with various forms of N. Fertilizer, however, is not the only source of N that can cause contamination of surface waters. Biological N fixation, mineralization of soil organic N, and animal wastes can also contribute to N enrichment of water bodies. Additionally, under some conditions, N applied to the soil may be converted to gaseous or immobile forms of N that do not contribute to surface water contamination. Because of these various sources and transformations of N, the severity of surface water contamination by N fertilizer has been difficult to precisely quantify. Research indicates that the amount of contamination from fertilizer varies depending on the amount of fertilizer applied, and characteristics of the soils, crops, climate, and the receiving water bodies.

PROBLEMS CAUSED BY N POLLUTION OF SURFACE WATERS

There are three water quality concerns associated with different forms of nitrogen (N). Firstly, the combined concentrations of nitrate (NO_3^-) plus nitrite (NO_2^-) in excess of 10 mg N L^{-1} can contribute to methemoglobinemia (“blue baby syndrome”) in infants if ingested.^[1] To guard against this, the U.S. Public Health Service limits NO_3^- plus NO_2^- concentration in public drinking water supplies to 10 mg N L^{-1} . Secondly, unionized ammonia (NH_3) may be toxic to fish at concentrations as low as 0.02 mg N L^{-1} . Finally, elevated total N concentrations (including NO_3^- , NH_3 , and organic forms) in rivers can promote the process of cultural eutrophication in coastal waters, whereby increased production and decomposition of algae, leads to reduced oxygen concentrations. This, in turn, may reduce the abundance and diversity of marine life and may promote the outbreak of nuisance algae.^[2]

SOURCES OF N POLLUTION

N contamination may come from a variety of sources: municipal sewage, animal manure, atmospheric deposition, biological N fixation, soil organic N, and/or N fertilizers. The consequences of contamination in a specific water body will depend upon the amount of contamination from all sources and characteristics of the receiving waters. Shallow rivers, wetlands, lakes, and reservoirs have some capacity to remove N by microbial denitrification. The susceptibility of estuaries and coastal waters to eutrophication depends on temperature, availability of phosphorus and

silica for algae production, and the rate of water exchange with the open ocean.

FERTILIZERS

The contribution of inorganic fertilizer to surface water N contamination increased after 1960 as the widespread and intensive use of inorganic N fertilizers rapidly expanded.^[3] The use of N fertilizer has allowed greater production of feed and food crops per unit area cultivated. In the United States, 75% of N fertilizer is applied to maize, while in other countries, N fertilizer is primarily used on wheat and rice. Prior to 1960, N for crop production was obtained primarily by using crop rotations that included legumes such as clover and alfalfa, which can establish a symbiotic relationship with soil bacteria that can convert atmospheric N_2 gas to biologically available forms of N.

Commercial N fertilizer is primarily manufactured as gaseous NH_3 , using the Haber–Bosch process in which gaseous N is reacted with gaseous hydrogen under pressure. The gaseous NH_3 may be injected into the soil, which is a common fertilizer application practice in the United States. Additionally, a wide variety of granular and aqueous fertilizer products containing N are manufactured from manufactured NH_3 .

WHAT HAPPENS WHEN FERTILIZER IS APPLIED TO SOIL?

Biochemical Processes

In the soil, NH_3 reacts with water and is largely converted to ammonium (NH_4^+), which tends to be strongly adsorbed

on soil particles. This adsorption inhibits the movement of NH_4^+ through the soil. NH_4^+ is an energy rich substance and certain soil bacteria can utilize this energy by decomposing the NH_4^+ to NO_3^- . Unlike NH_4^+ , NO_3^- is not adsorbed to soil particles and, therefore, moves readily with water in the soil. NO_3^- that is not taken up by plant roots or soil microorganisms can be transported to groundwater and surface water by a variety of mechanisms.

Hydrologic Processes

Rainfall, snow melt, or irrigation water input to the soil periodically exceeds the water-holding capacity of the soil in the root zone. Depending on the characteristics of the soil, this may lead to one or more of the following: 1) saturation of the root zone with water; 2) surface runoff; and 3) drainage of water through the soil profile to groundwater and/or surface water bodies. Each of these has different consequences for transport of NO_3^- to surface waters.

If the soil becomes saturated, oxygen may become scarce and in anoxic conditions, denitrifying bacteria may convert the NO_3^- to N gases (NO , N_2O , and N_2). N converted to these gases becomes unavailable for plant uptake or for surface water contamination. Additionally, saturated soil during the growing season is harmful to many crops like maize that cannot tolerate low oxygen concentrations in the root zone for more than a few days.

Surface runoff has the capacity to transport soil, vegetation, and surface applied granular fertilizers from agricultural fields to surface water bodies. If a granular form of N fertilizer had been applied immediately prior to the event that caused the surface runoff to occur, NO_3^- and NH_3 concentrations in runoff can be very high.^[4] However, this does not appear to be a common phenomenon. Small rainfall events are much more common than large events that typically produce surface runoff. After granular fertilizer is applied, it is likely that a series of small rainfall events will dissolve the granules and move the N into the soil profile, where it is less likely to contaminate surface runoff. Surface runoff usually has a low NO_3^- concentration but it can be high in organic and particulate N derived from soil and vegetation.

Drainage of water through the soil profile to groundwater and surface water appears to be the hydrologic pathway that most frequently leads to problematic NO_3^- contamination of surface waters in agricultural watersheds. This can occur in two ways: by natural drainage where ground water contributes to stream flow and river flow and by artificial subsurface drainage, where perforated pipes (sometimes called tile drains) have been buried in the soil for the purpose of removing water to reduce damage caused by saturated conditions and thereby enhance crop production (Fig. 1).

Artificial subsurface drainage improves aeration of the soil root zone and increases the length of time that machinery can be used on the soil.^[5] It is a common practice in the

Fig. 1 Illustration of the hydrologic cycle with artificial subsurface drainage (tile runoff) contributing to surface channel flow.

Source: From Steinheimer, Scoggin, et al.^[6]

North Central United States, and in northwestern Europe, where flat and swampy land has been converted to cropland. The water removed from the soil by artificial drainage is usually directed to surface ditches, streams, and rivers. This water can have high concentrations of N, principally in the NO_3^- form, especially where N fertilizers are applied in excess to the amount necessary for crop production.^[7,8] This NO_3^- can also be derived from microbial conversion of soil organic matter to inorganic N in the process of mineralization. Mineralized soil organic N may come from crop residues (unharvested leaves, stalks, and roots). Of course, some of the N in crop residues may have originated from fertilizer applied in previous years, but it can also derive from biological N fixation or animal manures applied on a field.

SPATIAL VARIABILITY

In most agricultural settings, commercial fertilizer provides only one source of N used for crop production. Animal manure, biological N fixation, mineralization from soil organic N, and deposition of N from the atmosphere can also contribute to soil fertility and surface water contamination. Because there are multiple sources and sinks of N in the soil, the relationship between N fertilizer application rate and N loss in drainage water is not always consistent across locations and across studies. If denitrification and plant and microbial uptake of N are large, NO_3^- concentrations in subsurface drainage may be low in spite of high fertilizer N inputs. If mineralization of soil organic matter is large, N in drainage water may be large without N fertilizer input. High rates of mineralization of soil organic N occur

after the initial cultivation of virgin land, and after a leguminous forage crop such as alfalfa or clover is cultivated into the soil. Appropriate use of N fertilizer should take all of these N sources into account, as should studies examining the relationship between N fertilizer use and water quality.

WATERSHED SCALE ANALYSES

Regional N Input–Output Analyses

Howarth et al.^[9] developed an approach for estimating the net N inputs to a region N that is highly correlated with average N transport in the rivers draining temperate regions (Fig. 2). Net N input to a region was defined as sum of N in fertilizer used, biological N fixation of agricultural crops, oxidized N in atmospheric deposition in the region, and the N in food and feed imported to the region minus the N in food and feed exported from the region. This approach assumes that there is no net gain or loss of N from soil organic matter. This assumption appears to be reasonable in regions where most soils have been under continuous cultivation for 60 years or more, at which time, annual mineralization of soil organic N is roughly replaced by organic N returned to the soil in crop residues and microbial biomass.^[10]

In temperate regions, riverine N transport was on average 25% of the net N input to the region. The fate of the other 75% of the net N is unknown, but much of it is probably converted to gaseous forms of N by microbial denitrification. The high net N input in countries draining to the North Sea, most notably the Netherlands, is in part

Fig. 2 Average annual riverine total N flux as a function of net anthropogenic N inputs to temperate regions draining to the North Atlantic Ocean.

Source: From Howarth, Billen, et al.^[9]

due to high density of domestic animals as well as use of N fertilizers. In tropical regions, riverine N flux was much greater than 25% of net N inputs, even in regions where little N fertilizer was used. The reasons for this are not precisely known but it is believed to be due, in part, to greater rates of biological N fixation in both cultivated and non-cultivated land in the tropics. This may also be due to the conversion of forest, wetlands, and grasslands to crop production, which leads to high rates of mineralization of soil organic N to NO_3^- that is highly mobile.

Hydrologic Process Models

The quantity of NO_3^- transported in rivers is also related to the quantity of water flowing in the rivers per unit of land area, which is also known as water yield. Caraco and Cole^[11] demonstrated that riverine NO_3^- N transport in major rivers in the world was a function of water yield, fertilizer use, population density, and atmospheric deposition of oxides of N. Building on these results, McIsaac et al.^[12] developed the following model of annual NO_3^- discharge in the Lower Mississippi River 1960–1998:

$$\text{NF}_m = 0.66\text{WY}^{0.93}e^{(0.13\text{NNI}^{2-5} + 0.06\text{NNI}^{6-9})} \quad (1)$$

where NF_m = annual NO_3^- N flux in Lower Mississippi River ($\text{kg N ha}^{-1} \text{yr}^{-1}$), NNI^{2-5} = average annual net N input during the previous 2–5 years ($\text{kg N ha}^{-1} \text{yr}^{-1}$), NNI^{6-9} = average annual net N input during the previous 6–9 years ($\text{kg N ha}^{-1} \text{yr}^{-1}$), and WY = annual water yield (m yr^{-1}).

This equation accounted for 95% of the annual variation in NO_3^- flux in the Mississippi River from 1960 to 1998 and suggested that riverine NO_3^- in a given year was correlated with net N input averaged over the previous 2–9 years. Furthermore, calculations with the model suggest that if the N fertilizer use in the basin had been 12% lower than actual during this period, NO_3^- flux to the Gulf of Mexico would have been 33% less than observed

(Fig. 3), assuming crop yields were not limited by N shortages.

The Role of Fertilizer Use Efficiency

The efficiency of fertilizer used for maize production in the major maize producing states (Illinois, Iowa, Indiana, Minnesota, and Nebraska) in the Mississippi River Basin increased between 1986 and 2000. Maize yields have increased about 20% from 1986 to 2000, while N fertilizer use has remained roughly constant. Between 1976 and 1986, an average of 0.023 kg N of fertilizer was applied for each kilogram of maize harvested. Between 1996 and 2000, an average of 0.018 kg N of fertilizer was applied per kg of maize harvested. If this improvement in fertilizer use efficiency had not occurred, NO_3^- flux in the Mississippi River in 1996–1998 would have been about 50% greater than the measured flux, according to the model of McIsaac et al.^[12] (Fig. 3).

Farmers face two major uncertainties when making fertilizer application decisions: they do not know what their yields will be nor how weather conditions might influence the availability of N fertilizer to the crop. The cost of N fertilizer has been relatively low in relation to the value of the increased yields, and consequently many farmers have believed that applying more N fertilizer than necessary provides “cheap insurance” against the uncertainties. In some instances, farmers did not consider N available from animal manure or from previously harvested legume crops like soybeans.

A number of factors are likely responsible for the increased fertilizer use efficiency. Research and outreach efforts have provided farmers with better information for making N fertilizer decisions. Water quality concerns have focused attention on the need for improved nutrient management. Weather during the 1990s was generally more favorable for corn production than the 1980s, when three major droughts occurred in the corn growing region of the Mississippi River Basin.

Fig. 3 Annual riverine NO_3^- flux in the Lower Mississippi River at St. Francisville, Louisiana, as determined from measurements (diamonds) as estimated from Eq. 1 (thick line), as estimated from Eq. 1 assuming a 12% reduction in N fertilizer input (thin lower line), and assuming fertilizer applications remained 0.023 kg N per bushel of harvested maize rather than declining to 0.018 kg N per bushel of harvested maize (thin upper line).

Source: From McIsaac, David, et al.^[12]

ADDITIONAL NEEDS AND APPROACHES FOR REDUCING N TRANSPORT

A improvement in the efficiency of N fertilizer use has also been observed in wheat production in the United Kingdom and rice production in Japan.^[3] However, improved fertilizer use efficiency alone may not be sufficient to address water quality problems in some settings. Jaynes et al.^[8] reported that even with N fertilizer rates at recommended levels, NO₃⁻ concentration in tile drainage water sometimes exceeded the drinking water standard of 10 mg N L⁻¹ in Iowa.

Zucker and Brown^[13] recommended several additional practices that can reduce N contributions in tile drainage: water table management, treatment of drainage water in wetlands, and use of crop rotations that reduce N losses. Additional monitoring and documenting the changes in water quality associated with changing fertilizer management practices are needed to improve our understanding of the connections between N fertilizer use and water quality in different geographic settings.

CONCLUSION

In many settings N enrichment of surface water bodies has increased following the increased use of N fertilizers. The precise contribution of N fertilizers to surface water N has been difficult to quantify because there are multiple sources of N contributing to most water bodies, and, depending on environmental conditions, a certain portion of soil N may be converted to gaseous or immobile forms. In general, however, agricultural regions with extensive artificial subsurface drainage systems or with sandy soils tend to have the most N enriched surface waters.

The efficiency of N fertilizer used for crop production increased in many areas in the 1990s and this has very likely limited or reduced the subsequent contamination of surface waters. Continued improvements in fertilizer use efficiency, and the use of wetlands for removing N from surface waters will help alleviate problems caused by N enrichment. Additional monitoring and research are needed to more precisely quantify how N management practices influence surface water N concentrations in different settings. A more precise understanding of the causal relationships between N inputs to the land and the contamination of surface waters could provide more effective guidance for management, policies, and programs intended to protect aquatic resources while maintaining optimal use of land resources.

Sustainable Agriculture: Social Aspects

Frederick H. Buttel

Department of Rural Sociology, University of Wisconsin, Madison, Wisconsin, U.S.A.

Abstract

Agriculture—conventional and sustainable, “traditional” and “modern”—is intrinsically social (or socio-technical) in nature. The social character of agriculture is particularly apparent, particularly widely recognized, and particularly crucial in the case of sustainable agriculture. Any reasonable definition of sustainable agriculture include both social and economic as well as technological and ecological components; the roots of unsustainability and the pathways to sustainability are fundamentally social processes. This entry will provide an overview of the most fundamental social dimensions of sustainable agriculture.

THE DEFINITION OF SUSTAINABLE AGRICULTURE

It is widely agreed that sustainable agriculture is intrinsically a joint social and ecological construct. Thus, e.g., Ikerd^[1] stresses the “anthropocentric” as well as “eco-centric” nature of agricultural sustainability, noting that the essence of sustainable agriculture is that “we [in sustainable agriculture] are concerned about sustaining agriculture for the benefit of humans, both now and into the indefinite future.” Sustainable agriculture is an agriculture that is “ecologically sound, economically viable, and socially responsible.”^[2] Allen similarly emphasizes that a conception of sustainable agriculture that fails to recognize the role of people, social actors, social institutions, and social movements is a limited one.^[3]

Sustainable agriculture and organic farming are very closely related but are not exactly coterminous. Organic farming systems tend to be highly sustainable systems according to the ecological and social components of the definition of sustainable agriculture and are often quite economically viable as well.^[4,5] Many in the sustainable agriculture community, however, feel strongly that sustainability improvements in mainstream or conventional agriculture are as important as the expansion of organic farming and organic agro-food systems.

STRUCTURAL CAUSES OF THE LACK OF SUSTAINABILITY

Agricultural sustainability is not only a vision of the long-term goals for agriculture, which imply measuring sticks for or indicators of its achievement.^[6] Sustainability also implies a critique of or a set of concerns about “conventional” agriculture—that mainstream agriculture has shortcomings in terms of environmental soundness, economic soundness, and social justice—and suggests that there have

been trends over time that jeopardize the achievement of these three ends.

The historical U.S. pattern of abundant land, limited and/or relatively expensive rural labor, and a strong tendency toward overproduction and low commodity prices has encouraged a capital-intensive, chemical-intensive monocultural system with a very high degree of enterprise and spatial homogeneity (or specialization). Commodity, trade, and public research policies have historically reinforced these tendencies to monoculture, specialization, and heavy reliance on chemicals, leading to an agriculture that has significant shortcomings on all of the criteria implied in the definition of sustainable agriculture.^[7]

SUSTAINABILITY AND THE CORPORATE INDUSTRIAL AGRICULTURAL ECONOMY

Agricultural sustainability cannot be considered apart from the globalized and highly concentrated corporate economy within which sustainable agriculture, and agriculture, as a whole, is enmeshed. Corporate concentration on input provision, food processing, and retailing limits the choices available to sustainable and other farmers. Corporate control over agriculture is increasing through processes such as the disappearance of “open markets” for agricultural products; the extension of vertical integration and contractual relationships; and the ever closer alignment of multinational chemical and seed companies on the one hand and food processors, manufacturers, and global trading companies on the other.^[8] There is evidence that the increased corporate domination of agro-food systems has negative implications for achieving agricultural sustainability. Farmer contractees, for example, are typically directed contractually by “integrators” to use particular practices that, more often than not, are unsustainable.

It should be stressed, however, that corporations—often small ones, but also large firms—have been major agents in

extending the scope of organic food production and organic marketing. There are two major nationwide organic chain grocery stores, and a number of corporations have been very successful in producing organic products such as potatoes, grapes, and fresh fruits and vegetables. The corporate organization of the organic food industry represents a major dilemma for proponents of agricultural sustainability. Highly successful sustainable agriculture ideas will be attractive to private corporations, which will often be successful in diffusing products and practices. At the same time, corporate agricultural sustainability practices may undermine certain aspects of the sustainability agenda (e.g., large-scale monocultural production of organic potatoes in the Northern Intermountain states is associated with a considerable threat of soil erosion and loss of biodiversity).

There is considerable debate in the sustainable agriculture community as to whether the best indicator of the growth of sustainable agriculture is the national market share of organic food—much of which is due to the activities of very large corporations such as Whole Foods—or whether the extent of sustainable agriculture is most accurately measured by the prevalence of community-supported agriculture (CSA), farmers markets, local co-ops, community gardens, and direct marketing of food. Those with the strongest commitments to sustainable agriculture are also most likely to see food system localization and the recreation of more local “foodsheds” as the heart and soul of a genuine and enduring sustainable agriculture.^[9]

SUSTAINABILITY AS A SOCIAL MOVEMENT

Agricultural sustainability is as much a social movement as it is a set of technologies and production practices. Social definitions of sustainability—that is, the concerns, views, ideologies, and agendas of movement participants—are as or more important in shaping what sustainability is as ecological or biological indicators such as soil erosion rates, levels of soil organic matter, biodiversity, and levels of runoff. What has put sustainability on the national and global agenda is primarily the organization and activities of the following three major types of groups: farmer-driven sustainable agriculture organizations and movements, consumer-driven or consumer-oriented sustainable agriculture initiatives (such as many CSA farms and most food co-ops and local food councils), and national and global environmental groups. Environmental groups have arguably done the most to increase the visibility and persuasiveness of the overall notion of sustainability, and of the particular concept of agricultural sustainability, though farmer-oriented groups do not always agree with environmentalists’ agendas for agricultural sustainability.

Each of the three main types of sustainable agriculture organizations, however, agrees on the main components of

the movement agenda: the need for more public research on sustainable practices, the need for public policy incentives for sustainability, the desirability of family farming, and the imperative to improve the environmental performance of agriculture. Increasingly, this consensus has extended to issues such as opposition to major trade liberalization agreements (the World Trade Organization and the North American Free Trade Agreement) and opposition to genetic engineering of crops and foods.^[10]

PUBLIC POLICY AND THE FUTURE OF AGRICULTURAL SUSTAINABILITY

Three necessary but insufficient conditions for the continued advance of sustainable agriculture are the development of improved sustainable technology; the presence of a vigorous and dynamic sustainability movement; and the development of a public policy environment that reduces the public policy disincentives to an environmentally sound, socially responsible, and economically viable agriculture. Of these three conditions, the public policy environment of agricultural sustainability is arguably the most important over the long term, even though the macro-public-policy environment is difficult to redirect, and there are areas of public policy disagreement among farmers, consumers, and environmental actors in the sustainable agriculture community; e.g., some sustainability advocates, particularly those in the environmental community (and some farm groups in that community), believe that the federal (and global) levels of action are most important or efficacious, whereas others believe that at this time the local (community or regional) arena is where advocates can most easily make a difference. Nonetheless, it is apparent that over the long term sustainable agriculture cannot advance far in a public policy environment that involves the strong disincentives to sustainability that prevail. There is a need for more active federal, state, and local regulation of both the on-site and the off-site impacts of agriculture; for ending the commodity-driven pattern of federal agricultural policy that shovels the lion’s share of subsidies in the direction of large, monocultural producers of overproduced commodities; and for redirection of the public agricultural research agenda. Some of the most innovative public policy ideas in sustainable agriculture are being developed in Europe. Green payments, taxes on pesticides and fertilizers, and the embracement of a “multifunctionality” approach to government agricultural policy are particularly promising policy instruments.^[11] Each of these policy instruments would support sustainability and yield other benefits (reduced government outlays, rural development, and reduced greenhouse gas emissions). There are no technocratic shortcuts to sustainability. Sustainability is, and must remain, as much a social movement as it is a set of practices and measuring sticks of agro-food system performance.

Abstract

Sustainable agriculture is a way of farming that can be carried out for generations to come. This long-term approach to agriculture combines efficient production with the wise stewardship of the earth's resources, including land management to maintain or enhance the quality of agricultural soils. Over time, sustainable agriculture is expected to meet human needs for food and fiber; protect the natural resource base, preventing the degradation of soil, water, and air quality and conserving biodiversity; use non-renewable resources efficiently; work with natural biological cycles and controls; and assure the economic survival of farming and the well-being of farmers and their families. Thus, the concept of sustainability embraces three distinct but overlapping areas of concern: social, economic, and environmental factors. Taking a holistic ecosystem approach to agriculture is the key to integrating these components of sustainability.

INTRODUCTION

Growing human populations, diminishing non-renewable resources, social and political instability, and environmental degradation threaten the natural processes that sustain the global ecosphere and life on earth.^[1,2] With losses of farmland to degradation and urbanization and little new agricultural land to develop, meeting the needs of future populations for food, fiber, and other agricultural products depends on a significant increase in crop yields. Under food production practices, this yield increase spells greater use of inputs (e.g., energy, fertilizer, and pesticides) and raises the question of the environmental costs of increased production.

AGRICULTURE AND ENVIRONMENTAL SUSTAINABILITY

To a large extent, the economic and social viability of agriculture depends on the sustainability of the resources that agriculture both depends on and affects. Farmers have always intuitively known that good soil quality underpins the success of their operations, and soil conservation programs in many countries throughout the 20th century supported this recognition. Since the late 1980s, interest has grown in a fuller accounting of the environmental costs of agricultural production. These costs include declining water quality and competition for finite water resources, declining air quality, emission of greenhouse gases, loss

of wildlife habitat, and decline in species and genetic diversity.^[3] To a large extent, conserving and enhancing soil quality can mitigate these costs.

Soil

Agricultural land management in the past has taxed the soil system, often withdrawing more than it has returned. In particular, mechanical cultivation and the continuous production of row crops have resulted in the displacement and loss of soil by erosion, large decreases in soil organic matter, and a concomitant release of carbon (C) as carbon dioxide into the atmosphere.^[4] The inventories of soil productive capacity indicate human-induced degradation on nearly 40% of the earth's arable land as a result of land clearing, extensive soil cultivation, soil erosion, atmospheric deposition of pollutants, overgrazing, salinization, and desertification.^[5] The projected doubling of the human population in the 21st century threatens even greater degradation of soils and other natural resources.^[6]

Water

Intensive farming practices have, in many parts of the world, jeopardized the quality of surface water and groundwater through the addition of agriculturally derived nitrate nitrogen (N), phosphorus (P), pesticides, sediment, and pathogens (e.g., bacteria from manure). Agriculture is considered the most widespread contributor to non-point-source water pollution in the United States.^[7] The major

agricultural water contaminant in North America and Europe is nitrate N derived from atmospheric deposition, livestock manures, and commercial fertilizers. Human alterations of the N cycle have almost doubled the rate of N input to terrestrial ecosystems over the past years, resulting in large increases in the transfer of N from land to the atmosphere and to rivers, estuaries, and coastal waters.^[8–10]

Agriculture, competing as it does with many other uses of freshwater, is also at the heart of discussions of water quantity and is a key consideration in the trend toward demand management, rather than supply management, of water resources. Global warming scenarios predict water shortages in some existing agricultural areas in the world, and water surpluses in others. Changing conditions will call for new ways of farming and of resolving conflict among water users.

Controlling soil erosion reduces the amount of sediments entering waterways, along with the chemicals (e.g., pesticides) and pathogens they carry. Nutrient management plans that account for all sources of N and P and match nutrient application more closely to plant needs reduce the risk of N and P entering groundwater and surface water. Maintaining soil quality improves the ability of soil to receive and partition water, making the most efficient use of this resource.

Air and Atmosphere

Atmospheric concentrations of greenhouse gases—particularly nitrous oxide, methane, and carbon dioxide—have been increasing dramatically over the past years, enhancing the greenhouse effect by which the earth's atmosphere is warmed. Agriculture is a significant contributor of these gases to the atmosphere; in Canada, e.g., agriculture accounted for about 10% of total 1996 emissions of these gases, an increase of about 4% since 1981.^[11] Soil management practices such as tillage, cropping patterns, and the use of manure and commercial fertilizers influence atmospheric quality through changes in the soil's capacity to produce or consume greenhouse gases.^[12,13] Under the United Nations Framework Convention on Climate Change and its protocols, signatory countries are considering ways to reduce emissions, including those from agriculture, and also to capitalize on agricultural sinks of greenhouse gases, such as by C sequestration in agricultural soils. The threat of ozone depletion and global climate change necessitates a better understanding of the influence of land management on soil processes.

Agricultural emissions of ammonia (from fertilizer and manure) and particulate matter (dust released during soil tillage and subsequent erosion) have been linked to various environmental effects, such as acidification, eutrophication, and smog. Reducing the emission of these substances involves improving the quality of soils so that they are more resistant to erosion, reducing tillage, increasing the amount

of soil cover, and practicing better N management (both manure and commercial fertilizer).

Agroecosystem Biodiversity

Agriculture benefits from biodiversity in many ways, but it has also reduced biodiversity over the years, mainly through the conversion of natural habitats, but also through effects on soil and water quality. Improving soil quality not only maintains a healthy biological community in the soil itself, along with the functions these organisms carry out, but also supports the other flora and fauna dependent on this community. Soil quality improvements that benefit water quality can also improve the viability of aquatic ecosystems.

ASSESSMENT OF SOIL QUALITY

Assessment of soil quality or health is invaluable in determining the sustainability of land management systems.^[14] Soil quality is the major link between the strategies of conservation management practices and the achievement of the major goals of agriculture.^[15,16]

Assessment of soil quality can be used to identify problem production areas, make realistic estimates of food production, monitor changes in sustainability and environmental quality as related to agricultural management, and assist government agencies in formulating and evaluating sustainable agricultural and land use policies (Fig. 1). Using simple indicators of soil quality and soil health that have meaning to farmers and other land managers is likely the most fruitful means of linking science with practice in assessing the sustainability of land management practices.^[17]

Fig. 1 The politics of soil health. The assessment of soil condition/quality is needed to monitor changes in sustainability and environmental quality as related to agriculture management and to assist governmental agencies in formulating realistic agricultural and land use policies.

Doran et al.^[18] stressed the importance of holistic management approaches that optimize the multiple functions of soil, conserve soil resources, and support strategies for promoting soil quality. They proposed a basic set of indicators to assess soil quality and health in various agricultural management systems. Many of these key indicators are very useful to specialists (e.g., researchers, consultants, extension staff, and conservationists) but are beyond the expertise or time constraints of the producer to measure. Success in developing and implementing standards for assessing soil quality and sustainability hinges on partnership with agricultural producers, who are the primary stewards of the land and the chief decision-makers regarding land use and management. In light of this consideration, Doran et al.^[18] also presented strategies for sustainable management that include a more generic set of indicators to assess soil quality and health that are practical for producers (Table 1). A study conducted in the northern U.S. corn and dairy belt used a similar approach to determine how farmers assess soil quality and health and found that they ranked soil organic matter, crop appearance, and risk to erosion as the three most important properties for describing soil health and sustainable management.^[17] Such strategies maximize the benefits of natural cycles, reduce dependence on non-renewable resources, and help producers identify long-term goals for sustainability that also meet short-term needs for production. Soil quality assessment must be directed at the financial survival of the farm as well as environmental preservation.

Although much remains to be done, useful models exist for translating soil science into practice; e.g., Gomez et al.^[19] provide a practical framework for determining the

sustainability of hill country agriculture in the Philippines. It uses indicators that satisfy both the needs of the farmer (e.g., productivity, profitability, stability, and viability) and the conservation of soil and water resources. Threshold values for sustainability are identified relative to the average local conditions for crop yield, profit, risk of crop failure, soil depth, percent soil cover, and soil organic matter content. This conceptual framework for assessing sustainability could be expanded to include other needs of society and environmental conservation. In particular, adding a category for balancing energy input and output, as well as monetary costs, would better assess the short- and long-term sustainability of management and the value of greater reliance on renewable resources and less dependence on fossil fuels and petrochemicals in enhancing economic, ecological, and environmental resources. Expanding the list of resource conservation variables to include leachable salts (especially nitrate), measured as soil electrical conductivity at the time of fertilization and after harvest, would permit land managers to better quantify the impact of agricultural practices on air and water quality.

Confirmation of the effectiveness of systems for residue management, organic matter formation, N and C cycling, soil structure maintenance, and biological control of pests and diseases will assist in discovering approaches that are both profitable and environmentally sound. The challenge in the future will be to better use the diversity and resiliency of the soil biological community to maintain a quality ecosystem, thus fostering sustainability. Sustainability strategies must be fine-tuned using such practices as crop rotation for greater crop diversity and tighter cycling of nutrients, reduction of soil disturbance to maintain soil

Table 1 Strategies for sustainable agricultural management and proposed indicators of crop performance and soil and environmental health.

Sustainability strategy	Indicators for producers
Conserve soil organic matter through maintaining soil C and N levels by reducing tillage, recycling plant and animal manures, and/or increasing plant diversity where C inputs C outputs	Direction/change in organic matter levels with time (visual or remote sensing by color or chemical analysis) Specific organic matter potential for climate, soil, and vegetation and soil water storage
Minimize soil erosion through conservation tillage and increased protective cover (residue, stable aggregates, cover crops, and green fallow)	Visual (gullies, rills, dust, etc.) Surface soil properties (topsoil depth, organic matter content/texture, water infiltration, runoff, ponding, percent cover)
Balance production and environment through conservation and integrated management systems (optimizing tillage, residue, water, and chemical use) and by synchronizing available N and P levels with crop needs during the year	Crop characteristics (visual or remote sensing of yield, color, nutrient status, plant vigor, and rooting characteristics) Soil physical condition/compaction Soil and water nitrate levels Amount and toxicity of pesticides used
Better use of renewable resources through relying less on fossil fuels and petrochemicals and more on renewable resources and biodiversity (e.g., crop rotations, legumes, manures, and integrated pest management)	Input and output ratios of costs and energy Leaching losses/soil acidification Crop characteristics (as listed above) Soil and water nitrate levels

Source: From Postel.^[2]

organic matter and reduce erosion, and development of systems that make greater use of renewable biological resources. Ultimately, the indicators of soil quality and strategies for sustainable management must be linked to the development of management systems that foster reduction in the inputs of non-renewable resources, maintain acceptable levels of productivity, and minimize impact on the environment.

Abstract

Sustainability is generally understood to mean a state or condition that allows for the fulfillment of economic and social needs without compromising the natural resources and environmental quality that are the foundation of human health, safety, security, and economic well-being. Sustainable development is both a *goal* of achieving this state for the benefit of existing and future generations and a *process* whereby innovative tools, models, and approaches are adopted to advance economic prosperity while minimizing adverse global impacts. Many case studies of business and government show that adopting sustainable practices can both enhance economic growth and protect the environment and social well-being. The need for sustainable approaches to business and economic development is made more urgent by increased rates of degradation and depletion of natural resources and by growing threats to human health and the environment. These stresses will only increase as the global population grows from 7 billion people to 9 billion by 2050. The practice of sustainable development is essential for reaching the next level of environmental protection, social development, and economic progress. This entry identifies some key origins of sustainability in the United States and around the world and concludes with eight steps toward achieving sustainable development.

INTRODUCTION

Sustainable development was defined in a 1987 UN report as “economic and social development that meets the needs of the present without compromising the ability of future generations to meet their own needs.”^[1] The concept of “sustainability” has been widely characterized as resting on three pillars: social well-being, economic prosperity, and environmental protection (Fig. 1).

As described in a 2011 report from the U.S. National Research Council, sustainability can be viewed as both a *goal* and a *process* that improves the economy, the environment, and society for the benefit of existing and future generations.

As a *goal*, sustainability is aimed at meeting society’s basic economic and social needs without undermining the natural resource base and environmental quality that are necessary for continuing to meet these needs in the future. Sustainability also describes the *process* whereby innovative tools, models, and approaches are applied in order to meet that goal, striving to advance economic prosperity while protecting natural resources. From the perspective of business and finance, sustainability as both a goal and a process aims to create value for shareholders and society

while efficiently using resources and minimizing adverse effects on the environment.

In the United States, the concept of sustainable development has roots that are over a century old. President Theodore Roosevelt relied on Gifford Pinchot, Roosevelt’s chief forester and the “father of American conservation,” for advice to develop public land policies in the late 1890s. Pinchot believed that forests should be made to serve the nation’s future as well as its present. He was an early advocate of sustainable development, writing in his 1910 book, *The Fight for Conservation*, “the central thing for which conservation stands is to make this country the best possible place to live in, both for us and for our descendants.”^[2]

Nearly 50 years later, the National Policy and Environmental Act established in 1969 the national goal of creating and maintaining “conditions under which [humans] and nature can exist in productive harmony, and fulfill the social, economic and other requirements of present and future generations of Americans.”^[3]

Sustainability has been investigated worldwide, as the Club of Rome composed of European economists and scientists published “The Limits to Growth” in 1972.^[4] This controversial report highlighted the negative impact of economic growth on the environment and served as a

Fig. 1 The three pillars of sustainability.

signal warning of the need for strategic planning in economic growth and environmental protection. The concept of sustainability was developed at the 1992 Earth Summit in Rio de Janeiro, where 179 nations endorsed the principles of Agenda 21, which declared, “The right to development must be fulfilled so as to equitably meet developmental and environmental needs of present and future generations.”^[5]

Twenty years after the Earth Summit, corporate, government, and non-governmental leaders converged again in Rio de Janeiro in June 2012 to examine and reaffirm commitments to global sustainability. The meeting provided a timely opportunity to further develop a common understanding of sustainability and how it can improve the lives of people in all countries around the world.

Sustainability is incorporated in many government goals and policy objectives. The European Union has been promoting sustainability since 2000, when it formulated the Lisbon Strategy with the goal of achieving the most competitive and dynamic knowledge-based economy in the world. The European Council has stated, “Clear and stable objectives for sustainable development would present significant economic opportunities and the potential to unleash a new wave of technology innovation, generating growth and employment.”^[6]

Sustainability has been advanced in the United States largely through Presidential Executive Orders such as 13423 under George W. Bush and 13514 under Barack Obama. Both orders set specific targets and goals for how the U.S. government should manage its own facilities. Federal procurement policies also reflect sustainability goals, their requirements for purchasing green and energy-efficient products.^[7]

The United States has sought to promote sustainability internationally through the first presidential “Policy Directive on Global Development,” whose aim is to focus on sustainable development outcomes that “place a premium

on broad-based economic growth, democratic governance, game-changing innovations, and sustainable systems for meeting basic human needs.”^[8]

Around the world, sustainable business practices are advocated by such varied organizations as the Global Reporting Initiative, the CERES coalition, and the United Nations Environmental Programme. At the state and local levels, an association of over 1220 local governments from 70 different countries known as ICLEI—Local Governments for Sustainability provides technical consultation, training, and information services to implement sustainable development.^[9] Many cities in the United States have adopted sustainability goals and a number of states have established governing bodies responsible for advancing sustainable practices.^[10]

A SENSE OF URGENCY

Global Footprint Network’s *Living Planet Report 2010* notes that humanity’s ecological footprint has more than doubled since 1966.^[11] This footprint represents the pressures on land and water area caused by the industrial and lifestyle patterns of human population. A challenge for global society is to “decouple” this global footprint from continued economic growth.

World population is expected to reach 9 billion people by 2050.^[12] Almost all of the increase will take place in the developing nations, where hundreds of millions of people are seeking more secure access to food, clothing, and shelter as well as sanitation, education, health care, energy, communication, and consumer goods. Coupled with the increasingly high levels of resource consumption in developed nations, this will place significant stress on global ecosystems. Ironically, the pressures on natural resources in developing nations could impede industrialization and further aggravate income gaps between rich and poor.

In addition to its impact on global warming, the inexorable growth of the global economy is contributing to a number of disturbing trends: sea level is rising, available fresh water and arable land are growing scarce, forests are disappearing, and biodiversity is threatened by changing natural habitats. The impacts of population growth and economic development are detailed in the 2005 Millennium Ecosystem Assessment, which found that 15 of 24 important global ecosystem services are being degraded or used unsustainably.^[13]

Accomplishing sustainable development in an increasingly interconnected global economy will require a holistic “systems approach” to problem solving, as shown in Fig. 2. The challenge of sustainability is to enable continued economic growth while reducing the rates of both resource use and waste generation. For example, companies that import components and feedstocks from overseas must be mindful of the potential environmental and social impacts in their supply chains. Considering the direct and indirect effects of

Fig. 2 Systems view of sustainability.

Source: From Center for Resilience, The Ohio State University.

sustainability policies and strategies will help avoid unintended adverse consequences.

OPPORTUNITIES FOR POSITIVE CHANGE

Sustainable practices can enhance and support economic growth. Many businesses have recognized the importance of sustainable practices to support a growing economy. Reducing the use of resources typically leads to reduced purchasing and operating costs, so companies generally view sustainable development as enhancing their bottom line while reducing their environmental footprint. In addition, sustainability enhances shareholder value by improving brand image, reputation, and stakeholder relationships. According to the Dow Jones Sustainability Indexes: "Sustainability is a business approach that creates long-term shareholder value by embracing opportunities and managing risks that derive from economic, environmental and social developments."^[14]

Sustainability strategies have been incorporated into the management objectives of major companies around the world.^[15] A 2009 study published in the *Harvard Business Review* concluded that "sustainability is a mother lode of organizational and technological innovations that yield both bottom-line and top-line returns" and that "there is no alternative to sustainable development."^[16]

The World Business Council for Sustainable Development (WBCSD) has developed an ambitious agenda to assist global industries in moving toward sustainable growth. The WBCSD Vision 2050 report coined the phrase "green race" and outlines a "pathway that will require fundamental changes in governance structures, economic frameworks, business, and human behavior." The report argues that these changes are "necessary, feasible, and offer tremendous business opportunities for companies that turn sustainability into strategy."^[17]

Financial industries including banking, investment, and insurance have also recognized the importance of sustainability and protection of natural resources. For example, the Equator Principles, launched in Washington in June 2003, require that banks assess the social and environmental impacts of projects that they finance. The principles were initially adopted by 10 global financial institutions: ABN AMRO Bank, N.V., Barclays plc, Citi, Crédit Lyonnais, Credit Suisse First Boston, HVB Group, Rabobank Group, The Royal Bank of Scotland, WestLB AG, and Westpac Banking Corporation.

Influenced by advocacy groups such as the Rainforest Action Network, Citigroup has gone beyond the Equator Principles by committing to refuse funding for projects that could result in illegal logging, other environmental damage, or harm to indigenous people.^[18] A report from the non-profit organization CERES lays out a road map for

sustainability based on assessing the company's baseline environmental and social performance, analyzing corporate management and accountability structures and systems, and conducting a materiality analysis of risks and opportunities.^[19]

While these corporate and institutional commitments are valuable, scientific and technological innovation will be critical elements in achieving genuine progress in sustainability. The required scientific knowledge to apply a systems approach will come from many disciplines—including chemistry, biology, and physics as well as economic and social sciences. New approaches such as “transdisciplinary” research and “sustainability science” have been introduced to describe the fusion of multiple disciplines to generate new knowledge, which is important for advancing sustainable innovation.^[20]

There are many excellent examples of innovations that dramatically improve the sustainability of products and processes. For example, traditional wood adhesives often contain formaldehyde, which is toxic to humans. Researchers have been able to develop new adhesives from soy flour, which are environmentally friendly, stronger, and cost-competitive. These new adhesives have replaced more than 50% of formaldehyde-based adhesives and earned a Presidential Green Chemistry Challenge Award.^[21]

Finally, it is important to assure the continued resilience of environmental, economic, and social systems in the face of turbulent change. *Resilience* is defined as the capacity not only to absorb disturbances but also to adapt and reorganize in order to maintain or improve functional capacity.^[22] In order to cope with unpredictable events, whether caused by humans or nature, infrastructure and supply chain systems must be designed for long-term resilience. One example is harnessing ecosystem services to provide “green infrastructure” that helps to protect community-based water resource systems from storms, floods, and other climate disruptions.^[23]

EIGHT STEPS TO SUSTAINABILITY

Sustainability represents the next level of environmental protection.^[24] In previous centuries, the traditional approaches to environmental issues focused on land conservation and risk mitigation. However, the 21st century brings a new set of environmental challenges that are more complex and globally interconnected. These new challenges demand new, more integrated approaches that account for the linkages among environmental resources, national security, human well-being, and economic competitiveness. In addition to regulatory approaches, a variety of strategies to achieve both sustainability and resilience, including public-private collaboration, integrated systems thinking, technological innovation, and adaptive management will be needed.

Effective working toward global sustainability incorporates these eight steps.

Take the Long View

Sustainability requires long-term thinking not only in natural resource management and urban development but also in corporate strategic planning. Taking a long view leads us to consider emerging pressures on ecosystems at different scales of resolution, and how the built environment and ecosystems can be managed in a synergistic way. For industrial innovators, the long view involves thinking about new business models in which material and energy resources can be used more effectively, while wastes and hazardous residuals can be reduced or eliminated.

Understand the System Dynamics

At all levels of society, humans participate in many different complex systems. As a growing population and consumption increase pressures on the ecosystem and the world becomes more tightly connected, small perturbations or changes in any one system can quickly cascade to other systems. Traditional industrial and engineering systems were not created with a systems view and may therefore be vulnerable to unexpected disruptions, such as natural disasters, industrial accidents, sabotage, or terrorism. By understanding system vulnerabilities and leverage points, we can develop cost-effective and resilient management strategies.

Define Sustainability Goals

President Kennedy sets a goal for the United States to land on the moon. This goal was achieved because it was fully supported with the needed resources and policies. Making sustainable development, an explicit policy goal at all levels of government, as well as the private sector, can send a clear message about the need for breakthrough innovation and creative regulatory and compliance approaches that serve the collective interests of the public, business, and government. A commitment to sustainable development can be a driver for a new generation of technology and policy innovation that restores U.S. leadership in the global economy.

Use Effective Tools

In order to practice sustainable development, advanced tools and approaches are necessary. Science and technology are key underlying contributors, along with innovative environmental and economic policies. New instrumentation, data handling, and methodological capabilities have expanded our understanding of the environment and of how complex biological, chemical, and human systems interact. A growing body of economic and environmental

assessment tools is available to support planners and decision makers at all levels of government and industry.

Find the Right Collaborators

Around the world, collaboration and partnerships among stakeholders are crucial to achieving solutions that are less polarized, more economically viable, and focused on balancing short- and long-term goals. Collaboration has begun among government, industry, and non-governmental organizations, and has already yielded many sustainable innovations.

Lead by Example

The profound changes needed to achieve sustainability will require confidence and bold leadership. The most persuasive approach for overcoming uncertainty and hesitation is leading by example—demonstrating that these changes are both realistic and beneficial. Government can help by establishing framework conditions and incentives that encourage innovation and by initiating collaborative pilot projects that bridge knowledge gaps and overcome inertia.

Measure and Track Progress

The use of sustainability indicators is essential for an integrated systems approach to the multifaceted challenges of sustainability. Indicators can help managers and policy makers anticipate and assess key trends, provide early warning of potential disruptions, quantify progress toward sustainability goals, and support decision making about complex trade-offs. A broad spectrum of available indicators is available that captures the economic, environmental, and social attributes of the systems that we strive to manage.

Learn and Adapt

The path to sustainability cannot be planned precisely due to the enormous complexity and uncertainty inherent in global political, economic, social, and natural systems. To navigate this path successfully, we cannot cling to preconceived notions or prescriptive solutions. We must be prepared to learn from experience, rethink our assumptions, and continuously adapt to change. Taking a resilient approach in the short term will enable sustainability in the long term.

CONCLUSION

The approach to energy use and resource management is not sustainable. Moving from the status quo toward sustainability requires new approaches to problem solving that take an entire system into account, rather than isolated

components. The challenge of achieving sustainability is urgent since unsustainable behavior—whether it is economic, social, or environmental—can lead to national and global crises. For example, when withdrawal rates from freshwater aquifers exceed recharge rates, water scarcity is the eventual result. Conversely, sustainable practices can preserve and protect natural capital and enhance economic growth. The challenge of realizing sustainability goals raises a number of practical questions: “What kind of government policies and business strategies can advance us toward sustainability?” “How can business and government work together to advance sustainable practices?” and “What can citizens do to advance the concept of sustainability?” Making sustainability operational is not something a government or business can do alone. A sustainable and thriving economy will require the convergence of four major elements: 1) regulations and policies, 2) advances in science and technology, 3) green business practices, and 4) public support and participation. A global commitment to accelerate movement toward sustainability is essential to safeguard social well-being, shared prosperity, and our natural environment. There is really no alternative.

Tailings: Minerals Processing Residue Rehabilitation

Lloyd R. Hossner

Soil and Crop Sciences Department, Texas A&M University, College Station, Texas, U.S.A.

Hamid Shahandeh

Texas A&M University, College Station, Texas, U.S.A.

Abstract

There are large areas of abandoned mine tailings from a variety of industrial operations around the world. Tailings contain a large proportion of the original ore that was mined. Tailings are deposited in impoundments with dimensions ranging from several square meters to some that are many square kilometers in area. These tailings have been largely abandoned and allowed to revegetate under natural conditions. There have been both public and scientific awareness of the possible consequences of long-term disposal of tailings. A complete understanding of the physical and chemical properties of tailings is essential for planning successful rehabilitation programs.

INTRODUCTION

Metals have been mined and exploited with the growth of world industry. In particular, iron, lead, zinc, and copper have been mined extensively in regions all over the world. In the process of metal beneficiation, massive heaps of spoil (tailings and waste rock) have been created at mine sites or areas distant from mines (Fig. 1). Tailings and waste rock create esthetic problems in the landscape and affect water, soil, plant, and public health. Tailings is defined as the solid waste product of the milling and mineral concentration process.^[1] Mill tailings are the finely ground host rock materials from which the desired mineral values have been extracted during the concentration process. Generally, tailings are transported from the mill to their place of disposal as a water slurry containing 15–50% solids by weight and discharged by impoundment on land in settling ponds adjacent to the mills, used as backfill in the open pit or underground mine, disposed in deep lakes or offshore, or processed for secondary metal recovery followed by disposal. Tailings impoundments range in size from <10 to >2000 ha and may be stacked as high as 50 m.^[2]

There are a large number of abandoned mine waste and tailings deposits from a wide variety of industries around the world. The total area of land disturbed by mining in China is estimated to be about 2 million hectares.^[3] In the United States between 1930 and 1980 more than 2 million hectares of land were affected by mining operations.^[4] The mine tailings produced in Malaysia, England, Thailand, and Canada are estimated

in billions of tons occupying hundreds of thousands of hectares.^[2]

POTENTIAL ENVIRONMENTAL PROBLEMS

Abandoned spoil and tailings contain the waste products of both mining and ore processing operations. Chemical extractants such as sulfuric acid and sodium bicarbonate are used for uranium ores, cyanide for gold ores, sodium hydroxide for aluminum ores, and sulfuric acid and hydrochloric acids for copper, nickel, and cobalt ores. In addition to these toxic solvents and the dissolved heavy metals, tailings from uranium and phosphate operations can contain radionuclides such as thorium and radium. These materials are often a major source of pollution in the local environment due to dust blow and the potential leaching of the products of mineral weathering into water sources.

Tailings are also subject to the process of weathering and, over time, changes may occur in their properties which could be hazardous to the environment. For example, sulfides are associated minerals that are readily oxidized in the tailings when exposed to air, water, and iron-oxidizing bacteria. One of the oxidation products is sulfuric acid. Tailings containing sulfide minerals may eventually have a pH of 1.5–3.5.^[2] Toxic ions may also contaminate soils and waters adjacent to smelters through seepage, runoff waters, and eroded sediments. Effluents arising from tailings seepage could be toxic in varying degrees to man, animals, and plant life. Also, there is a concern for the amount of heavy metal uptake by plants growing on tailings and its effect on the food chain.^[5]

Fig. 1 Mine/mill environment.

Source: From Ritcey.^[2]

MINE WASTE REHABILITATION PRACTICES

Engineering Approach

Mine waste residue and soils contaminated with toxic metals and radionuclides can be remediated and stabilized using engineering approaches including chemical, physical, and thermal techniques (e.g., *in situ* mobilization, immobilization, degradation, and burial; or removal and reburial, vitrification, vacuum extraction, steam flooding, pumping and leaching, electroosmosis, and electroacoustic extraction).^[6] The use of chemical and physical techniques to stabilize mineral wastes against wind and water erosion is limited because of the cost and maintenance.^[7] Physical stabilization of materials such as waste rock from strip mining can be used to reduce wind and water erosion.

Chemical stabilization requires a chemical agent, such as lignin sulfate or resinous adhesive, to react with mine waste to provide a crust resistant to wind and water erosion. Physical stabilization can be performed by protecting or isolating the waste from the environment with physical barriers such as liners and clay caps. Usually, the design and installation of a cover system consists of three zones: an erosion resistant layer, a moisture retention layer, and an

underlying clay barrier to prevent entrance of water into the waste material. The design of the capping sequence and incorporation of a coarse layer to break capillarity are shown to be very important. When waste material poses a threat to groundwater quality or to plant growth, a layer of impermeable plastic or compacted clay may be placed between the waste and the soil cap to prevent movement of water into the toxic wastes. In other materials, it may be necessary to place a diffusion barrier of very coarse material between the toxic waste and the cover soil to break a water column that might permit diffusion of the toxic materials from the waste into the cover soil. Soil caps placed over non-toxic materials may be thinner than soil caps placed over toxic materials.^[8]

Ecological Approach

According to the Center for Minesite Rehabilitation in Australia, the strategies for rehabilitation of mine waste should be based on stabilization and sustainable revegetation of tailings and waste rock in a reconstructed ecosystem.^[9] Tailings must be stabilized before or concurrent with full-scale revegetation. The keys to successful revegetation of metalliferous mill tailings are: 1) obtain a complete understanding of the physical and chemical properties of the tailing material; 2) select an appropriate final land use of the area under consideration; 3) select the most cost effective combinations of amendments, nutrient supplements, cover materials, and plant species to be employed; and 4) monitor the performance of the vegetation and make adjustments as needed. It is widely accepted that the establishment of vegetation is a desirable method for stabilization of mine wastes.^[10,11] Vegetation reduces wind velocity at the surface, captures dust particles, reduces raindrop impact, reduces runoff by increasing infiltration, and reduces the overland flow of water and sediment. Vegetative stabilization also improves the chemical, biological, and physical properties of the mine wastes by increasing the organic matter content, nutrient level, cation exchange capacity, and biological activity.

Vegetation established on mine tailings has several advantages over physical and chemical methods of stabilization. Vegetation is esthetically pleasing and accepted by the public, relatively inexpensive, less disruptive of site remediation, creates a beneficial habitat for wildlife, plant roots and shoots can take up heavy metals, and plants may stimulate microbial immobilization of heavy metals in the rhizosphere. Thus, establishment of vegetation in mining areas has the potential of reducing contamination of adjacent soil, surface water, and ground water.^[8]

The main approaches to revegetation have been summarized in Table 1.^[7] The waste characteristics of a site determine which approach is most suitable. Generally there are two approaches to revegetation which have been used in

Table 1 Approaches to revegetation of minerals processing residue (tailings).

Waste characteristics	Reclamation technique	Problems encountered
Low toxicity: total metal content <0.1%. No major acidity or alkalinity problems	Amelioration and direct seeding with agricultural or amenity grasses and legumes. Using traditional or specialized techniques	Probable commitment to a medium/long-term maintenance program. Grazing management must be monitored
Low toxicity and climatic limitations: toxic metal content <0.1%. No major acidity or alkalinity problems, extreme of temperature, rainfall, etc.	Amelioration and direct seeding with native species. Seed or transplant ecologically adapted native species using amelioration treatments where appropriate	Irrigation often necessary at establishment. Expertise required on the characteristics of native flora
High toxicity: toxic metal content >0.1%. High salinity in some cases	1) Amelioration and direct seeding with tolerant ecotypes. Apply lime, fertilizer and organic matter, as necessary, before seeding 2) Surface treatment and seeding with agricultural or amenity grasses and legumes. Amelioration with 10–50 cm of innocuous mineral waste and/or organic material. Apply lime and fertilizer as necessary	Regular fertilizer application. Few species have evolved tolerance and few are available commercially. Grazing management not possible Regression will occur if depths of amendments are shallow or if upward movement of metals occurs. Availability and transport costs may be limiting
Extreme toxicity: very high toxic metal content. Intense salinity or acidity	Isolation: surface treatment with 30–100 cm of innocuous barrier and surface binding with 10–30 cm of a suitable rooting medium. Apply lime and fertilizer as necessary	Susceptibility to drought according to the nature and depth of amendments. High cost and potential limitations of materials availability

Source: From Tordoff, Baker, et al.^[7]

combination or separately. They are adaptive and ameliorative approaches. The adaptive approach to revegetation is to combat the toxicity of the waste by direct seeding with metal tolerant cultivars. The metal tolerant plants may be of great benefit to developing countries for low-cost revegetation. The other approach is ameliorative and the toxicity is avoided or diluted, rather than tolerated by using some form of covering system. This approach has been widely used and subjected to considerable research. The two types of covering material are ameliorants and inert amendments. Ameliorants are materials such as sewage sludge, compost, domestic refuse, peat, and topsoil. Inert ameliorants include materials such as clay, shale, or gypsum. Inert ameliorants are commonly wastes from other industry or mining activities. This approach has the added benefit of using one category of waste to overcome the problems of other forms of waste.^[12]

Although revegetation is desirable, metal wastes can present a very unfavorable environment for plants because of the presence of many growth limiting factors such as high salinity, metal toxicity, or nutrient deficiency in the mine tailings and soils.^[13]

CHARACTERISTICS OF MINE WASTE THAT LIMIT REHABILITATION

Characteristics of tailings from 43 selected mine waste sites are presented in Table 2.^[14] Alleviation or modification of each chemical and physical limitation of the tailing is required prior to the establishment of vegetation.

Chemical Properties

The chemical composition of tailings depends on the original ore mineralogy, extraction techniques, and associated minerals. Among the minerals present in tailings, sulfides are often an important constituent that must be considered in tailings management.

Mining often exposes the sulfide-bearing minerals (pyrite, marcasite, pyrohotite, chalcopyrite, arsenopyrite, cobalite) to the atmosphere. In the presence of water, iron sulfide oxidation by weathering (Eq. 1) and by iron oxidizing bacteria catalysis (Eq. 2) will convert the sulfides to sulfuric acid.^[15]

Large amounts of lime, between 10–150 t ha⁻¹, may be required to neutralize the acidity produced in sulfidic tailings.^[5]

Various salts may appear on the surface of tailings depending on the nature of the original mill process. The factors which are involved in the appearance of salts on the tailings surface include: excess concentrations of soluble salts in tailings materials, availability of shallow subsurface water, salt concentrations within the tailing water, and temperature and chemical potential gradients between the surface and the interior of the tailing. The upward migration of

Molybdenum (Mo)	mg/kg	70	10–800
Nickel (Ni)	mg/kg	96	10–546
Lead (Pb)	mg/kg	340	0.3–2,810
Titanium (Ti)	mg/kg	2500	200–10,000
Zinc (Zn)	mg/kg	510	1–5000
Copper (Cu)	mg/kg	130	1–750

salts and their inhibiting effect on root growth and revegetation have been major concerns in the reclamation of many mine tailings. For example, a common problem associated with the establishment of vegetation in asbestos tailings, bentonite tailings, and red mud from bauxite ore processing for alumina is salinity and/or sodicity. These wastes can be highly alkaline (pH > 10), saline (EC > 30 dS m⁻¹), and sodic. Vegetation establishment on these tailings is difficult because of salinity, alkalinity, clay dispersion and low hydraulic conductivity.^[5]

Mine wastes are usually deficient in major plant nutrients and almost universally deficient in nitrogen. Nutrient deficiencies, especially nitrogen, phosphorus and potassium, are often the principal limiting constraints to revegetation of kaolinitic china clay, iron, copper, gold, silver, and other heavy metal mine wastes.^[5] The success of establishing plants on tailings depends on providing an adequate supply of plant nutrients. High levels of the major essential nutrients may reduce the harmful effects of metal ions.

Toxic ions are frequently present in tailings of heavy metals in sufficient concentrations to prevent plant growth unless considerable amelioration is undertaken. Toxic ions decrease root respiration, limit water and nutrient uptake, reduce enzymatic activity and microbial populations, and inhibit cell mitosis in root meristematic regions.^[15] Toxic ions may also contaminate soils and waters adjacent to tailings through seepage, runoff waters, and eroded sediments. Another problem with heavy metal contaminated tailings is the possible uptake of metals by plants in quantities that could be toxic in the general food chain. Radioactivity associated with uranium and phosphate tailings and high concentrations of arsenic, mercury, and cyanide in silver and gold mine tailings are other environmental concerns.

Physical Properties

The physical properties of tailings vary with the mineral being processed, the origin of the ore body, and the process used for mineral concentration. Physical properties are the most important in determining productivity of vegetated mine wastes because of the cost involved in trying to ameliorate particle size distribution and water-holding capacity. Non-uniform texture is the main physical problem of mine wastes which limits the availability of water to plants. Mining generates a wide range of particle size materials. This includes coarse mine wastes, fine clays, flotation tailings, chemical precipitates, and slimes. In the mineral industry the slime size fraction is < 5 µm.

Fine texture is a major problem in gold tailings. Gold tailing is finely crushed (0.01–0.1 µm) because of the large surface area needed for fast reaction with processing chemicals. It is relatively easy to establish vegetation on these tailings but it is difficult to obtain full ground cover because young plants are sand blasted by finely crushed, wind

blown materials. Laying large rock fragments on the slope of sand deposits and installing reed wind breaks on the entire sand deposit has helped the establishment of vegetation.^[2] A critical factor in reclaiming and vegetating a tailing is the availability of moisture for plant growth. Moisture curve characteristics of tailings derived from iron, nickel, copper, lead, zinc, and gold mines showed properties similar to a sandy loam soil, an indication of potential water deficiency for plant growth.^[2]

Vegetation establishment and maintenance on coarse tailings, where there will be little water retention and rapid drainage, are also related to water availability. Establishment of vegetation on very coarse tailings is difficult but it can be achieved by adding a soil cover followed by hydro-mulching and hydroseeding.^[15]

Crusting, cracking, and a general lack of structure are common characteristics of mine tailing brought about by differences in texture, lack of organic matter, and variable mineralogy. Structure determines the bulk density of tailings. Water infiltration is often limited in fine textured tailings due to poor structural characteristics. Root penetration and moisture stress of plants due to limited rooting generally becomes a problem with dry bulk density values above 1.5 Mg m^{-3} in tailings.^[15]

Tailings have a high heat capacity. Tailings exposed to direct solar radiation can have temperatures of 55–65°C at 1–2 cm depth. Internal temperature in a silver mine in Canada reached 45°C during the oxidation process. Hay or straw mulch has been an effective insulator for stabilizing the tailings temperature.^[2]

CONCLUSION

There are large areas of abandoned mine tailings from a variety of industrial operations around the world. Tailings contain a large proportion of the original ore that was mined. Tailings are deposited in impoundments with dimensions ranging from several square meters to some that are many square kilometers in area. These tailings have been largely abandoned and allowed to revegetate under natural conditions. There have been both public and scientific awareness of the possible consequences of long term disposal of tailings. Now many countries have enacted legislation to ensure reclamation of tailings of disposal sites once the mining and milling operations have ceased. A complete understanding of the physical and chemical properties of tailings is essential for planning successful rehabilitation programs.

Taxonomies: U.S. Soil Taxonomy and Indian Scenario

Tapas Bhattacharyya

Dr Balasaheb Sawant Konkan Krishi Vidyapeeth, Dapoli, India

Dilip Kumar Pal

Division of Soil Resource Studies, National Bureau of Soil Survey and Land Use Planning, Nagpur, India

Abstract

The National Bureau of Soil Survey and Land Use Planning (Indian Council of Agricultural Research) as a premier soil survey institute has been using the U.S. Soil Taxonomy (USST) to group Indian soils for agricultural land use planning. USST is a user-friendly platform for both pedologists and edaphologists because of its an open-ended system, which helped Indian soil scientists over the years to contribute their thoughts to enrich USST by describing Indian tropical soils by improvising its rationale. Major research findings show the Oxisols are more of a concept than reality. Classification of Indian soils has consistently been revised with special reference to low activity clay, saline, sodic, and hydromorphic soils.

INTRODUCTION

The U.S. Soil Taxonomy (USST) of the U.S. Department of Agriculture (USDA) is an elaborate, universally acceptable, hierarchical system of soil classification showing well-defined differentiating criteria based on measurable soil and associated land characteristics. Higher categories in USST depend on various properties that are produced by distinct soil-forming processes which are well defined by the nomenclature of different taxa. Moreover, USST is an open-ended system that accommodates new concepts developed over time. The system, as the soil itself, is dynamic as evidenced by its continuous revision since its inception^[1–3] which was adopted in India in 1969.^[4]

USST SOIL ORDERS IDENTIFIED IN INDIA

The soil resource mapping programme (1986–1996) in India generated database on soils, their area and characteristics following USST.^[5] Seven soil orders are reported from India. The occurrence of soil orders, sub-orders, great groups, subgroups, and families are detailed in Fig. 1. During the last two decades focus of research on Indian soils has changed qualitatively because mineralogical, micromorphological, and age-control tools have been used to measure the subtle pedogenetic processes of the present and past geological periods.^[6] It helped to understand the basic issues in soil genesis through USST for efficient use and agricultural management.

Black Soils (Vertisols) and Their Intergrades

Deep to very deep black soils (Vertisols), popularly known as black cotton soils, dominated by smectitic clays, are

characterized by the presence of either slickensides or wedge-shaped peds with $\geq 30\%$ clay and cracks that open and close periodically. A group of soils belonging to other soil orders possess the characteristics of black soils showing linear extensibility (LE) of 6.0 cm or more. High LE values are caused by smectitic clays that allocate these soils to vertic subgroup. The presence of slickensides is not a must for classifying a soil into vertic intergrades.^[3] Studies show that red Vertisols and their intergrades also exist, suggesting the term black soils for Vertisols and vertic intergrades are no more tenable and shrink–swell (SS) soils are appropriate to address them. The estimation indicates that Indian SS soils occupy nearly 76.4 Mha.^[5] Studies explained that the slow and steady process of haplodization induced by argillipedoturbation inhibits the process of horizonation and favors the development of Vertisols with characteristic cyclic horizons.^[4] Extensive pedological research during the last 15 years on Indian Vertisols shows clay illuviation as a more dominant pedogenic process than the argillipedoturbation thereby suggesting the subsoil horizon designation as B⁴ instead of A¹. Besides, soil taxonomists in India observed characteristics of the “mollic” epipedon in many benchmark Vertisols of central India.^[4,6]

For the manifestation of vertic properties, the minimum threshold value of clay smectite has been reported as 20. By and large, Indian Vertisols are calcareous and these calcareous soils cover 229 Mha area.^[4,6] Keeping in view the ill effects of excess carbonates on crop performance, USST has a provision for carbonatic mineralogy class at the family level for soils containing $>40\%$ carbonates. Interestingly, Indian soils with $>40\%$ carbonates are sometimes endowed with calcium (Ca)-rich zeolites which offset the ill effects of excess carbonates.^[4,6] In view of contemporary natural chemical degradation process in the presence of soil modifiers like Ca-zeolites and gypsum, the mineralogy

Fig. 1 Total orders (a), sub-orders (b), great groups (c), subgroups (d), and families (e) of Indian soils.

class in USST should, therefore, be based on pedo-edaphic data sets.^[4] The rationale for using exchangeable sodium percent (ESP) as 15 or more in one or more horizons within 40 cm of its upper boundary has been debated for diagnostic subsurface horizons like the natric.^[2] It has been observed that even an ESP of 5, highly smectitic Vertisols develop poor drainage that impairs crop productivity. This is in contrast to non-smectitic soils which do not have the drainage problem even at the ESP of 50 and above,^[4] and Indian Vertisols though that have ESP > 15, indicating their sodic character but do not affect crop growth because of the presence of natural Ca-zeolite.^[8] The lower limit of sodicity at ESP > 40 for soils of the Indo-Gangetic Plains (IGP) at ESP > 5 but < 15 for Indian Vertisols or the limit of ESP 6 for Australian soils or > 15 for all soil types appears to be redundant for the zeolitic sodic Vertisols of India. In view of the pedogenetic processes controlling the hydraulic properties of soils mediated through dispersibility, grouping soils on the basis of saturated hydraulic conductivity (Ks) appears logical using a threshold value of Ks < 1 cm h⁻¹.

Brown Forest Soils (Mollisols) in Tropical Climate

Acidic and fairly weathered Mollisols in the zeolitic Deccan basalt areas were reported in the hills of central and western India under forest in the tropical humid climate.^[9] Formation and persistence of Mollisols in the hills of central and western India expand the basic rationale of the USST for the formation of a group of organic matter-rich, dark-colored, Ca-saturated, soft, clayey, smectitic, but

acidic Mollisols. The formation of Mollisols in the zeolitic basalt landscape over millions of years and their persistence in central and western India demonstrate that the quality of parent materials prevents the transformation of smectite to kaolin, helps in the retention of adequate amount of smectite, and provides continuous supply of bases (Ca²⁺ ions) required for the formation of Mollisols even under tropical humid climate. The foregoing suggests that although the soils in the study area are formed in humid tropical climate for millions of years, they have not reached the advanced stage of weathering represented by Ultisols and Oxisols; instead, they have remained Mollisols.

Alfisols, Ultisols, Oxisols, and Their Classification

Owing to the serious difficulty for field identification of clay skins in highly weathered soils, the kandic horizon introduced in Soil Taxonomy was often used for classification of highly weathered humid subtropical soils in north-eastern India.^[4] The “kandi” group of Alfisols and Ultisols is common in India. The introduction of this subsurface diagnostic horizon and inclusion of “kanhapi” intergrade helped to group many low-activity clay Inceptisols into Alfisols (>35% base saturation) or Ultisols (<35% base saturation). Although the Inceptisols have been grouped properly as Kandi (c) Alfisols and/or Ultisols, the formation and existence of Oxisols have been debated.^[4,9] The kandic horizon provides a basis for differentiation among soils with clay accumulation in the subsoils. The presence of

an argillic horizon could not explain the diagnostic criteria to differentiate all Ultisols and Alfisols from Oxisols and Inceptisols. The proposed kandic horizon is such a diagnostic horizon that it can separate low cation exchange capacity (CEC) Ultisols and Alfisols from the high CEC Ultisols and Alfisols. The important property of Oxisols is that they should be almost devoid of weatherable minerals (<10%), and thus further weathering may not supply nutrients for sustaining plant growth. Moreover, the advanced stage of weathering might obliterate the boundary differentiation between horizons and as such clay films may be absent. The conditions for their formation in the tropical climate with stable landscape and siliceous/acidic parent material are available in the Indian subcontinent; Oxisols are not reported.^[4,9] An in-depth study of international reference on the laterites (Ultisols) in the state of Kerala indicated inconsistency in soil grouping (order) and the assignment of mineralogy class,^[10] and thus it was envisaged that the transformation of Ultisols to Oxisols with time could be difficult to reconcile not only in the tropical part of India but also elsewhere.^[4,9–11] Many of the micaceous soils of the IGP of northwestern India are sodic and have clay enriched textural B horizon without any clay skins and grouped in Inceptisol order. Decrease in clay mica (<2 μm) with depth in the profile can confirm clay illuviation for these soils to group them in Alfisols.^[4,11] A new subgroup (Alumic Hapludults) was proposed for soils of the Shillong Plateau, India, supporting the growth of pine forest with high extractable Al^{3+} content (>50%) in the Bt horizon. The concept of a Modic subgroup in Ultisols, showing an excellent environment for aerobic respiration, has also been proposed.^[4] In the humid tropical weathering environment in India, the presence of vermiculite/high charge smectite is common. Minerals in clay fractions have not weathered to reach the stage of kaolinite suggesting mixed mineralogy class as appropriate.

Inceptisols and their classification

Inceptisols occupy 40% and 15.2% in India and world, respectively.^[10,11] The concept of grouping shallow black soils into a Leptoveritic subgroup^[4] has finally found a place in the Vertisol order as Leptic Haplusterts.^[2] Out of the three types of saturation such as endo, epi, and anthric saturation,^[2] the first two found places in the great group (for instance, in Inceptisols, they are Endoaquepts and Epiaquepts, respectively). Anthric condition has been referred as a variant of episaturation, which is usually associated with controlled flooding (in India, e.g., for crops like wetland paddy). This condition causes reduction process in the saturated and puddled surface soils with alternate oxidation during unsaturated conditions. Although the “Anthraquic” condition has been included in Soil Taxonomy, this special type of saturation does not find any place in the great group/subgroup level. In absence of that, most of the soils in the IGP and other rice growing areas of India qualify for episaturation.^[4]

Salt-Affected Soils and Their Classification

The sodic (alkali) soils of the north-west part of the IGP with high salts, ESP, pH, chromas and yellower hues, key out as Typic or Aquic Calciorthids, Camborthids (Aridisols), and Haplustalfs (Alfisols), and this grouping does not spell out their saline-sodic nature to set these soils apart at some high categoric level in the system required for land use recommendations.^[4] Accordingly structural requirements for the Natric horizon were proposed to be modified to include horizons with high ESP (≥ 40) but having simple blocky structure with or without tongues of eluvial material. New subgroups, viz., Natric, within the orders of Inceptisols, Alfisols, and Aridisols, are suggested for the high sodium-saturated soils lacking Natric horizons. For similar practical considerations, the high concentrations of salts in soils when associated with high ESP pose problems in leaching and consequently new subgroups, viz., Salic and Salic Natric, within the orders of Aridisols and Alfisols, were suggested. Salt-affected soils occupy 6.65 Mha area in India, nearly 36% of which occur in the IGP.^[4] The soils of floodplains irrespective of containing water soluble salts are classified as Aquepts and Ustepts. Since USST^[5] may not serve the purpose of differentiating non-saline/non-sodic soils with saline and/or sodic soils with special reference to the IGP, India,^[4,6] sodic intergrade was proposed for soils with ESP >15. Similarly for the salt-affected soils of active alluvial plains of the IGP, Salic and Sodic intergrades were proposed at the subgroup level for the meaningful interpretation of soil management.^[4]

Paleosols and polygenetic soils and their classification

Paleosols are not covered by the Soil Taxonomy, since it was not endorsed by the USDA.^[2] Paleopedologists made efforts to apply Soil Taxonomy for the study of Paleosols. Paleosols are the soils formed in a geological age and can be either buried or non-buried.^[4] and can be either buried or non-buried. Soil Taxonomy recognizes a soil as buried when it is covered by new soil material of at least 50 cm thickness.^[2] The Paleopedological Sub-Commission recommended that only when the type or direction of soil-forming processes changes, the soils are recognized as Paleosols. Besides, there are polygenetic soils showing different diagnostic features indicating more than one climatic episode. Such soils, for example, ferruginous soils of southern Peninsular India, overlying the saprolites of metamorphic rocks, dominated by kaolinite or dioctahedral smectites have been reported as relict Paleosols^[8] and related color and ratios of various sand sizes with silt to indicate Paleosols from southern Peninsular India.^[4] These relict soils have been influenced by the climatic change from humid to drier conditions during the Plio-Pleistocene transition period.

Alluvial soils which are older than 2,500 years BP of the central IGP are relict Paleosols that experienced three climatic episodes during the Holocene period leading to different types of soils. A series of Vertisols in a climo-sequence (ranging from humid to arid bio climates), from Typic Haplusterts to Udic/Aridic/Sodic Haplusterts and finally to Sodic Calcicusterts, are in place to suggest that USST can be a useful tool to trace the signatures of climate change. Buried soils from Andhra Pradesh (AP), India, formed by allochthonous overburden, represent a double profile.^[4] A Thapto-Tropofluventic subgroup of a Vertisol (Haplustert) and of an Inceptisol (Ustropept/Haplustept) has been proposed. Soil Survey Staff^[5] used thapto (GK Thaptein meaning bury) to represent a buried Histosol or a buried histic epipedon, whereas “thapto” in AP soils was used to indicate any buried Entisol with fluvial characteristics in the tropical climate and also a Thapto-Haplustalfic subgroup for a buried Alfisol.^[8] There are efforts to identify the Paleosols according to the approaches of Soil Taxonomy, first by recognizing the diagnostic horizons and other pedogenic features. However, because many ancient buried Paleosols are often incomplete and difficult to reconstruct, even experienced workers find it difficult to recognize diagnostic features of the Soil Taxonomy or the Food and Agriculture Organization scheme. In spite of this difficulty, the paleopedology community favored developing a separate soil group.^[4]

CONCLUSION

Different kinds of soils in India indicate that the soil diversity is quite large because of variability of several factors of soil formation. USST helped to fine-tune the basic differences among Indian soils, since the concept of each taxonomic class has always remained purpose specific. Since inception, many researchers have found that the USST is useful in terms of grouping a particular type of soil and this has immensely enriched the soil classification literature to understand the basics of soils, in general, and tropical soils, in particular. Amid the renaissance in soil science, a massive demand would be to appropriately manage tropical soils for their restoration and preservation, and the USST has an important role to play in this endeavor.

Taxonomy

Mark H. Stolt

Department of Natural Resources Science, University of Rhode Island, Kingston, Rhode Island, U.S.A.

Abstract

Soil, like any natural resource, needs to be classified in order to best utilize and conserve the resource. As long as humans have lived in communities, soils have been classified. In most cases, the classification approach is strongly influenced by the concept that the most important use of soils is for agriculture. The taxonomic classifications of soil resource, however, can be applied to any number of use and management purposes when the classification is based on the physical, chemical, and morphological properties of the soils. As such, use and management assessment of soil resources are made through soil surveys based on taxonomic soil classifications. In this entry, the development and architecture of the soil taxonomic system used in the United States in the past years—Soil Taxonomy, are discussed. The discussion includes references and comparisons to other national classification systems and the international soil classification system known as the World Reference Base. Advances in soil classification and major issues are also discussed.

INTRODUCTION

One could argue that of all the natural resources, soil, water, and air are the only essential resources. Soil, like any natural resource, needs to be classified in order to best utilize and conserve the resource. Fanning and Fanning^[1] suggested fairly simple reasons for classification as follows: to provide a means to organize our knowledge and to provide a system to retrieve the information for any number of purposes. Soils have been classified for almost as long as humans have lived in communities.^[2] One of the primary reasons was to assess the land for agriculture; those with the best soils for agriculture were taxed the greatest amount because they owned the best land. Since such classification approaches were not designed around the natural physical, chemical, and morphological properties of the soils (taxonomic properties), but based on their productivity or other use assessments, these soil classification approaches are termed interpretive classification systems.^[1]

Agriculture is also the root of most soil taxonomic systems. For example, in Soil Taxonomy (the system used in the United States and many other areas of the world), in deciding which properties to be used as criteria for classifying the soil, the property with the most effect on agriculture is the one that is chosen.^[3] Although throughout history agriculture has driven the design of a soil classification system, there are many other uses of Soil Taxonomy. This is clear in the title of the U.S. soil classification system; although typically referred to as just “Soil Taxonomy,” the complete title is *Soil Taxonomy: A Basic System for Making and Interpreting a Soil Survey*. In every U.S. soil survey, there is a list of use and management interpretations for each soil taxa. These include

many non-agronomic interpretations such as use of the soil for construction materials, recreational purposes, supporting roads and buildings, waste disposal treatment, constructing earthen dams, and silviculture. Thus, the ultimate purpose of Soil Taxonomy is to provide a means to assess the potential of the soil resource to serve any number of purposes through soil surveys. In this entry, we will focus on taxonomic soil classification systems.

SOIL TAXONOMY OVER 20TH CENTURY

Soil science and taxonomy, as we know them, are little more than a century old. Prior to the late 1800s, soils were considered a surface mantle of loose and weathered rock.^[4] V.V. Dokuchaev, a Russian geologist working mostly between 1870 and the turn of the 20th century, articulated our existing concept of soil: a natural body that has formed over time through a series of physical, chemical, and biological processes acting upon a given soil parent material. These processes are governed by the landscape setting, climate, and soil biology. Jenny^[5] called these the five state factors of soil formation: climate, organisms, relief, parent materials, and time. Thus, soils, with similar parent materials and biology that have formed under similar climates and landscape settings, will have similar properties and thus taxonomic classification.

Of the taxonomic soil classification systems prior to the turn of the 20th century, Dokuchaev's system was the most influential. His works were translated to German by Glinka^[6] and later translated from German to English by C.F. Marbut.^[1,7–9] Marbut considered many of the ideas and concepts of soils at that time relative to mapping soils and

developed a classification system for the United States that was published in its final form in 1935.^[10] Followers of Dokuchaev, especially Sibertsev,^[11] further developed Dokuchaev's system that later became the foundation of the soil classification system that was used in the United States between 1938 and 1965.^[1] The 1938 Yearbook system^[12] was based primarily on Dokuchaev's concepts of soil orders which were named zonal, intrazonal, and azonal soils in the 1938 Yearbook.^[13] Schaetzl and Anderson^[14] called the 1938 Yearbook the first serious attempt of classifying soils in the United States. Zonal soils essentially matched the concept of "normal soils" described by Dokuchaev and more fully articulated by Marbut.^[15] Soils that have developed in better drained conditions over enough time to be considered to have reached maturity under existing climatic conditions. Azonal soils were the young soils developing in areas such as shallow to bedrock, floodplains, or aridic sands. Intrazonal soils were controlled by wetness or chemical composition such as salts. Examples and summaries of the 1938 Yearbook system can be found in Fanning and Fanning^[1] and Schaetzl and Anderson.^[14]

Although the 1938 Yearbook was used for many years in the United States, serious flaws were widely recognized in the system. There were six categories in the hierarchy, but the suborder (second) and family (fourth) categories went essentially unused.^[16] Likewise, the series-level category failed in the hierarchical scheme since it would not always match with a higher-level taxa. Some soils went unrecognized, such as some of those formed from volcanic ash or shrink-swell clays.^[1] Another issue was that classification was based on unaltered (virgin) soils; thus, a soil that had been cultivated or eroded was classified into a taxa that represented what it would have been like in a virgin form.^[14] Because of these issues, a more quantitative and less subjective system was needed.

In the early 1950s, Guy Smith began to work toward a new classification system.^[17] Over the next decade, six versions (labeled approximations) of the system were circulated among soil scientists mostly in the United States.^[18] The 7th Approximation^[19] was circulated worldwide at the World Soil Congress in 1960. At first, there was little acceptance of the new system, but Simonson^[20] noted regarding his paper published in *Science* "evidence of growing interest was indicated by requests for a few thousand reprints of my 1962 paper." By 1965, the system was adopted for U.S. Department of Agriculture–Natural Resources Conservation Service [USDA-NRCS; formerly known as Soil Conservation Service (SCS)] soil surveys and a decade later published as Soil Taxonomy.^[3]

A list of guidelines for the development of an effective soil classification system was given within the 7th Approximation^[19] and later revised for inclusion in Soil Taxonomy.^[3] In general, the guidelines suggested that the system be flexible enough that soils that were not

identified could easily be added; the system could be used worldwide; the properties used to classify the soil will be measured (not necessarily by instruments); the focal point of the properties measured is soil genesis related; if a choice needs to be made between which of two properties to use in the classification criteria, the one with the most effect on plant growth be used; and properties that are easily changed by anthropogenic activities such as plowing be only used at the lowest of levels when classifying the soil.

THE SOIL THAT WE CLASSIFY

Our concept of soil depends on our background and experiences;^[21] e.g., someone with a potted plant may say the plant is supported by soil, and many would agree. A soil scientist would argue that this concept of soil is analogous to saying a cup of water taken from the lake shore is a lake. No one would agree with that! Knox^[22] reviewed the various bodies of soil materials that could be considered soil. These ranged from individual particles, like a sand grain, to landscape-level bodies that could be mapped out at a 1:24,000 scale. That pot of soil materials described above would be considered a "hand specimen" by Knox.^[22] In this entry, we will use the USDA-NRCS^[23] definition of soil: a collection of natural bodies; composed of mineral and organic materials; and that supports the growth of plants out-of-doors or show evidence of soil-forming (pedogenic) processes. Within this context, our collection of natural bodies is the series of horizons that vary with depth and over an area of the landscape on the order of 1–10 m². Such a 3-D area of soil is called a pedon.^[19,21,24] Most soils are described using a 2-D view of a pedon, called a soil profile (Fig. 1). In most soil taxonomic systems, a pedon is the smallest soil unit that is classified.

SOIL TAXONOMY INTO THE 21st CENTURY

Soil Taxonomy has the following six hierarchical categories: order, suborder, great group, subgroup, family, and series (Table 1). The first five categories are set up as a key, so that every soil can be classified, and the last taxon in the key is the default. In most cases, classification to the order, great group, or subgroup level in mineral soils is predicated on the presence or absence of diagnostic horizons. Those diagnostic horizons forming at the soil surface are called epipedons. Subsurface diagnostic horizons are typically in the position of the B horizons in the profile. The standard for the epipedon is the mollic because soils with mollic epipedons typically are excellent for agriculture. Most of the soils in the Great Plains in the United States and the Steppe regions in Russia have mollic epipedons. These are the soils that Dokuchaev studied in Russia and formulated his early concepts of soils. Mollic epipedons are thick (typically 25 cm or more), dark in color, rich in organic matter, and rich in basic cations (base saturation >50%). Umbric

Fig. 1 (A) A Typic Epiaquod in Rhode Island. The tape is in inches. The spodic diagnostic subsurface horizon varies in thickness and depth. Near the tape, the spodic horizon occurs from 10 to 20 in. The soil is saturated to the surface for parts of year and thus the aquic suborder. The water is held, or perched, above a restrictive layer (epi) starting at 36 in. There are no other diagnostic features (typic). (B) An umbric Endoaquult in Pennsylvania. The soil has an umbric epipedon, an argillic diagnostic subsurface horizon, and a base saturation <35%. The soil is saturated throughout the profile and to the soil surface (Endoaqu) for extended periods of the year. The small marks on the tape are 10 cm increments. The large marks are in feet. (C) Fluvaquentic Eutrudept on a Pennsylvania floodplain. The tape is in centimeters. Fluvaquentic indicates that the soil is saturated during the year for a considerable amount of time above 60 cm, and there is buried soil organic carbon (note the buried A horizon between 80 and 90 cm). The soil has a cambic diagnostic subsurface horizon (20–80 cm) with a base saturation >60% (Eutr). The climate is humid and thus an udept. (D) Calcic Haplustalf in Texas. The small increments on the tape are 10 cm apart. The larger marks are one foot apart. The soil has calcic and argillic diagnostic subsurface horizons. The base saturation is greater than 35%, and the moisture regime is semiarid (ustic).

Table 1 The architecture of Soil Taxonomy.

There are six categories from the highest (least detail) to lowest (most detail) level: order, suborder, great group, subgroup, family, and series. The names for classes in the order, suborder, great group, and subgroup categories are all coined terms using Greek, Latin, French, or similar roots. The soil orders are listed in the order they key out; a limited number of examples are provided for the other categories.

Order: Names of the 12 orders consist of three or four syllables and every name ends in the suffix “sol.”

Order name	Formative element	Derivation
Entisol	ent	Nonsense syllable, think of recent
Vertisol	ert	L. <i>Verto</i> , turn, think of invert
Inceptisol	ept	L. <i>inceptum</i> , think of inception
Aridisol	id	L. <i>aridus</i> , dry, think of arid
Mollisol	oll	L. <i>mollis</i> , soft, think of mollify
Spodosol	od	Gk. <i>Spodos</i> , wood ash, think of Podzol*
Alfisol	alf	Nonsense syllable, think of Pedalfer**
Ultisol	ult	L. <i>ultimus</i> , last, think of ultimate
Oxisol	ox	F. <i>oxide</i> , think of oxide
Andisol	and	Gk. <i>Andes</i> , think andesite
Histosol	ist	Gk. <i>histos</i> , tissue, think of Histology
Gelisol	el	L. <i>gelare</i> , to freeze, think of gel

*Podzol—classic term used for soils with spodic horizons; **Pedalfer—one of the two taxa in Marbut's^[10] highest category.

Suborder: The name of every suborder is a two-syllable term consisting of a prefix syllable with some specific connotation plus the formative element from the order to which the suborder belongs. The examples are for Ultisols, Inceptisols, and Vertisols.

Formative element	Connotation	Example
Aqu	Aquic moisture regime	Aquult
Ud	Udic moisture regime	Udept
Ust	Ustic moisture regime	Ustert

Great group: The name of each great group is constructed by adding a second prefix element with a specific connotation to the two-syllable term that is the name of the suborder to which the great group belongs.

Formative element	Connotation	Example
Umbra	An umbric epipedon	Umbraquult
Eutr	High base status	Eutrudept
Calci	A calcic horizon	Calciustert

Subgroup: Names of subgroups are binomial. An adjective (sometimes two) is used to modify the name of the great group to give the name of each subgroup within that great group.

Adjective	Connotation	Example
Plinthic	Presence of plinthite	Plinthic Umbraquult
Arenic	Thick sandy surface	Arenic Eutrudept
Lithic	Shallow to rock	Lithic Calciustert

Family: A sequence of descriptive adjectives is used in family names. The common examples are used to describe particle-size classes, mineralogy classes, activity classes, and soil temperature classes.

An example is coarse-loamy, mixed, active, mesic, typic dystrodept. Coarse-loamy (particle-size class), mixed (mineralogy class), active (activity class), mesic (soil temperature class), aquic dystrodept (subgroup).

Series: It is a family that falls within a given range of characteristics. Series names are typically derived from towns or localities that are near where the soils are found (i.e., Newport). The range in characteristics is related to morphological properties such as thickness of the B horizons, soil colors, rock fragment contents, and soil textures. The range in characteristics is not found in Soil Taxonomy but can be accessed online: <http://soils.usda.gov/technical/classification/osd/index.html>

epipedons are similar to the mollic except more acidic, having a lower base status. Histic epipedons are typically 20–40 cm thick and dominated by organic soil materials. There are also folistic (unsaturated histic epipedons), melanic (associated with volcanic ash), plaggen (heavily manured for centuries), and anthropic (phosphorus rich from long-term human occupation) epipedons. In general, the ochric epipedon is the default, meaning soils that do not meet the criteria for the other six epipedons have an ochric epipedon (very new soils may have no epipedon).

In Soil Taxonomy, there are 18 diagnostic subsurface horizons. Only the more common are briefly discussed in this entry, so that the reader can understand the concept and follow the examples in Table 1. Most diagnostic subsurface horizons are related to the accumulation of soil constituents in the B horizon position of the soil profile. The accumulations may be of silicate clay (argillic), sesquioxides bound to organic matter (spodic), calcium carbonate (calcic), gypsum (gypsic), and salts more soluble than gypsum (salic). Certain diagnostic subsurface horizons are dense or cemented by the constituent that has accumulated such as petrocalcic, petrogypsic, or duripan (cemented by silica that has reprecipitated in the B horizon). Younger soils may not have had enough time to form any of the diagnostic horizons previously mentioned but have B horizons recognized by a simple change in color. These “color” B horizons typically meet the criteria for a cambic diagnostic horizon.

In keying out soils to the order level, Gelisols are the first possibility. The important criterion is the presence of permafrost (generally within a meter of the soil surface). Histosols key out next; these soils are dominated by organic soil materials (at least 40 cm) in the upper 80 cm. Spodosols follow, having spodic diagnostic horizons. Andisols have andic soil properties (high exchange capacity and water-holding capacity). Oxisols are extremely weathered and dominated by iron and aluminum oxides (oxic horizon). Vertisols are dominated by shrink–swell clays that results in a self-mixing soil. Aridisols may have a number of diagnostic horizons such as argillic, calcic, and cambic as long as they are in aridic (dry) moisture regimes. Ultisols have argillic horizons and low base saturation (<35%). Mollisols have mollic epipedons and a base saturation throughout the profile greater than 50%. These soils may have calcic or argillic horizons. Alfisols almost always have argillic horizons, but unlike Ultisols, their base saturation is >35%. Inceptisols are weakly developed soils typically with cambic horizons. Entisols are the least developed, characterized by a lack of diagnostic horizons or epipedons other than ochric, and key out last.

Because soil moisture (or lack of) has a dramatic effect on soil morphology, suborders typically bring the wetness attributes or soil moisture states related to climate (soil moisture regimes) into the classification (see examples in Table 1 and Fig. 1). These moisture regimes include aquatic

(wet), udic (humid), ustic (semiarid), and xeric (dry parts of the year and moist other parts).

There were only a few major changes to Soil Taxonomy over the years. In 1975, there were 10 orders; that was changed to 12 with the addition of Gelisols (soils with permafrost) and Andisols (soils formed in volcanic ash-type materials). The definition of soil was changed in the 2nd edition.^[25] Previously by definition, a soil was required to be able to support rooted plants.^[3] In the new edition, soils, as long as they showed evidence of pedogenesis, were considered soils even if they did not support rooted plants. This departure from the agricultural roots of Soil Taxonomy was designed to accommodate soils in the arctic that were permanently covered with snow or ice^[26,27] or soils that were permanently under water (subaqueous soils).^[28]

In 1983, field versions of Soil Taxonomy were first published. The field versions essentially just included what was needed to key the soil out to the family level, but much of the supplemental materials of the classification system were left out. These versions were called the *Keys to Soil Taxonomy*. As we learned more and more about the soils, changes in the taxonomy were introduced in revised versions of *Keys to Soil Taxonomy*. For example, taxa were included in the 11th edition of *Keys to Soil Taxonomy*^[23] to accommodate subaqueous soils.^[28] Although by design Soil Taxonomy was meant to be flexible enough so that new soils could be added when deemed necessary,^[3] some argue that over time it might be too big and cumbersome to be useful any longer. For example, the first *Keys to Soil Taxonomy*^[29] was a 4 in. × 9 in. paperback that easily fit in your back pocket for use in the field (<250 pages). By 1996, the 7th edition of *Keys to Soil Taxonomy* in the same 4 in. × 9 in. format was well over 600 pages.

One area of soils that continues to be difficult to classify in Soil Taxonomy is the anthropogenic soils (i.e., soils developed in materials moved by man).^[30] In an attempt to resolve this issue, the International Committee on Anthropogenic Soils (ICOMANTH) was formed with the charges defining appropriate classes in Soil Taxonomy for soils that have their major properties derived from human activities. The first activities of this committee were reported in the 1st circular letter dated 1995 (http://clic.cses.vt.edu/icomanth/03-AS_Circulars.pdf). Efforts of the committee resulted in new horizon designations for soils with restrictive properties because of the presence of a continuous man-made material such as cement (master horizon designation M) and horizons containing human artifacts such as glass, brick, or cement (subordinate horizon designation u). These changes appeared in the 10th edition of *Keys to Soil Taxonomy*.^[31] Suggestions for classifying such soils have primarily focused on subgroups such as spolic, urbic, or garbic^[1,32] or a separate order with Soil Taxonomy—Anthrosols.^[33] Efforts toward classifying anthropogenic soils continue through ICOMANTH such that there are seven circular letters describing proposals,

changes, and related activities of the committee (<http://clic.cses.vt.edu/icomanth/circlet.htm>).

OTHER NATIONAL AND INTERNATIONAL CLASSIFICATION SYSTEMS

There are numerous other taxonomic soil classification systems. Buol et al.^[34] reviewed a number of these including the Russian, French, Belgian, British, Canadian, Australian, Brazilian, and Chinese. Many of these systems take elements directly or indirectly from Soil Taxonomy.^[25] For example, at the order level, the Australian system uses “Organosols” instead of Histosols.^[35] Seven of the diagnostic horizons or features in the Chinese system are taken directly from Soil Taxonomy.^[36] The Chinese and Australian systems have soil orders for anthropogenic soils.^[35,36]

The World Reference Base (WRB)^[37] is the only true international soil classification system. This system, known as the WRB, was endorsed and adopted by the International Union of Soil Sciences as the classification system for soil correlation and international communication. The intention of the WRB was not to provide an alternative for any national soil classification system but to serve as a soil classification translator for communication at an international level.^[37] During the development of the WRB, a focused effort was put forth to include as much nomenclature from Soil Taxonomy^[25] and other major national soil classification systems, as possible.

The WRB is a two-tiered system. At the highest category are 32 reference soil groups. A number of these are essentially the same as the soil orders in Soil Taxonomy; examples of these include Vertisols, Histosols, Podzols (Spodosols), Cryosols (Gelisol), and Chernozems (Mollisols). Like Soil Taxonomy,^[25] diagnostic horizons are used as criteria in many of the taxa. Although their definitions are not identical, a number of the WRB diagnostic horizons are conceptually the same as those in Soil Taxonomy. Some examples include mollic, ochric, histic, gypsic, calcic, and cambic.

The second tier of the WRB is a series of qualifiers that are added as a prefix or suffix to the reference soil groups to identify in greater detail properties of the particular soil. Each reference soil group is assigned a list of qualifiers that may be used. In the WRB,^[37] an example is given for a Cryosol soil reference group: “Histic Turbic Cryosol (Reductaquic, Dystric).” Histic and turbic are the prefix qualifiers indicating that the Cryosol has histic epipedon and evidence of cryoturbation (mixing by freeze-thaw), respectively. Reductaquic and dystric are the suffixes indicating that the soil is both saturated and reduced and has a base saturation less than 50%, respectively. Unlike Soil Taxonomy,^[25] climatic parameters are not applied in the classification of soils in the WRB, and the system is not designed for mapping soils at resource-level scales.

SUMMARY AND CONCLUSION

Soil is one of the basic and essential natural resources. Thus, some form of soil classification has been around since humans formed communities. The early systems were primarily based on a use assessment of the soils for a single purpose such as agriculture productivity (i.e., low yields, moderate yields, or high yields). These systems are often referred to as interpretive soil classifications. The taxonomic classification of soils is based on the natural physical, chemical, and morphological properties of the soil and can provide many use and management interpretations. The application of taxonomic classification for soil resources is through the use of soil surveys. The best example of a taxonomic system for mapping and assessment of the soil resource is Soil Taxonomy. This is a hierarchical system that is set up like a key, so that every soil can be classified. There are six categories in the system with order the highest (least amount of detail) and series the lowest (greatest amount of detail). Although Soil Taxonomy is used worldwide, many countries have their own soil classification system. There is also a truly international system called the WRB. The WRB is designed as an international translator for systems such as Soil Taxonomy and was not meant to provide classifications for resource soil mapping.

Issues with Soil Taxonomy appear to be related to the lack of significant taxa for anthropogenic soils, its field applications, and the rapidly expanding number of taxa. Issues with field applications center around the need for considerable laboratory data to correctly classify a soil. A possible resolution is to develop guidelines based on reasonable assumptions that can assist the user in applying Soil Taxonomy in the field without any laboratory data. As we learn more and more about soils, the number of taxa in Soil Taxonomy continues to grow. Proposals are being considered to add taxa to accommodate the classification of some anthropogenic soils. Some users feel that continued additions leave the classification system too cumbersome to key through to find the correct taxa. Whether this is a problem or not is debatable, but correcting such a problem may require reformatting the hierarchical system. An approach to resolve this issue that is being considered is the new classification system using some of the format of the WRB and some of Soil Taxonomy. As the world's population continues to grow, resource managers will turn more and more to soils information to best utilize this essential resource. As such, developing an understanding of Soil Taxonomy will continue to be a need for natural resource users and managers.

Temperature Measurement

Kevin McInnes

Department of Soil and Crop Sciences, Texas A&M University, College Station, Texas, U.S.A.

Abstract

There is no set design either for construction or procedure for installation of soil thermometers, other than the requirement that they operate in a continuously moist environment. Soil thermometers may be tailored for measurement of either surface or subsurface temperatures. Surface temperature measurements are desirable because they can be used to estimate subsurface temperatures. Measurement of subsoil temperature is difficult because installation disturbs the soil and alters the thermal regime.

VARIABILITY OF SOIL TEMPERATURE

Soil temperatures generally fall between -20°C and 60°C , except in extreme environments. Mean diel soil surface temperature is usually the same as the mean diel air temperature. Similarly, the mean annual soil temperature is usually equal to the mean annual air temperature.^[1] Differences between extremes of the daily average surface temperatures vary from a few degrees near the equator to upward of 30°C or more in the mid-latitudes. For the diel cycle, differences between the periodic extreme surface temperatures depend on the nature of the soil cover. Bare soil produces the largest differences, with $15\text{--}30^{\circ}\text{C}$ being common. Both diel and annual patterns in temperature at the soil surface travel down through the soil where each magnitude is increasingly attenuated and each phase increasingly retarded with increasing depth.

Water in soil helps buffer against extreme temperature fluctuation. In the case of soil freezing, declining soil temperatures are buffered near 0°C by the latent heat of fusion. Once water is frozen, soil temperatures may drop as low as -40°C in extremely cold environments.^[2] Likewise, as soil temperatures rise under extreme heating, they are buffered by the latent heat of vaporization at temperatures near 95°C .^[3] When all moisture is lost under prolonged heating, as might occur under a slow-moving fire, interfacial soil temperatures may rise hundreds of degrees.^[3]

MEASUREMENT OF SURFACE TEMPERATURE

Surface temperature may be used to calculate subsurface temperatures with a fair degree of accuracy.^[4] Surface temperatures can be measured with or without direct contact. Non-contact thermometers infer temperature from the amount of thermal radiation emitted from the soil. Infrared thermometers (IRTs) measure temperature by capturing and quantifying the amount of thermal radiation emitted in a

narrow band of the infrared spectrum, typically $8\text{--}14\text{ }\mu\text{m}$. Soil temperature is related to the quantity of radiation emitted through the Stefan–Boltzmann equation and knowledge of the soil's thermal emissivity.^[5] As soil temperature is inferred from the amount of infrared radiation captured by the sensor, reflected background radiation introduces a source of uncertainty that must be considered. A soil's thermal emissivity changes with soil water content and surface roughness, whereas background radiation varies with air temperature, humidity, and cloud cover. Monitoring changes in emissivity and background radiation requires additional IRT measurements, adding to the complexity of the soil temperature measurements. A variation of the IRT used extensively in remote sensing is the infrared camera. An infrared camera provides detailed information on spatial variation in surface temperature that otherwise would be difficult to collect.

Contact thermometers used to measure surface temperature must have good thermal contact with the soil surface and minimally affect surface energy exchange. To satisfy both these requirements sensors may be coated with soil.^[6] The added soil provides weight that helps hold the thermometer in contact with the soil and gives the sensor similar emissivity and reflectivity as the soil.

TYPES OF SOIL THERMOMETERS

While non-electric contact sensors are used to measure soil temperature, the advent of accurate and reliable electronics has removed nearly all advantages they held over electric thermometers. There are several types of electric thermometers suited to measuring soil temperatures. Temperature probes made from thermocouples, resistance sensors, and integrated circuits (ICs) are most common. All these sensors easily function over the normal range of soil temperature.

Thermocouples are popular soil temperature sensors because they are robust and easy to construct. Thermocouples consist of two dissimilar metal wires joined to each other at one end, the sensing junction, and to the terminals of a meter at the other end. A difference in temperature between the sensing junction and the meter terminals results in a voltage that can be measured and converted to temperature provided the temperature of the terminals is known. There are eight different combinations of metals and alloys, designated as letter types, for which there are internationally accepted values of the relationship between voltage and temperature difference (referenced to 0°C). Modern thermocouple meters have these relationships built into their software. Industry-accepted errors in wire composition allow a specified degree of uncertainty in voltage output at a given temperature.^[7] Type T wire consists of copper and constantan conductors and is the most popular type for constructing soil thermometers. Manufacture with standard type T wire allows an error $\pm 0.8^\circ\text{C}$ from the calibration equation used in modern thermocouple meter software. This allowable error for type T is better than that for other types of thermocouple wire by a factor of approximately 2. A limited selection of special wires with tolerances half those of the standard wires (e.g., $\pm 0.4^\circ\text{C}$ for type T) is available.

Thermocouples may be connected in a series configuration called a *thermopile* to measure minute temperature differences, such as those associated with gradients inducing heat fluxes in soil or they may be combined in parallel to measure a spatial average temperature.^[8] Caution must be exercised when using a parallel configuration of thermocouples because improper construction may cause serious errors.^[8–10]

IC temperature transducers are a new class of thermometers. IC sensors are available with either a voltage or a current output. Both outputs are linearly related to temperature. Voltage output is typically 10 mV K^{-1} ,^[11] while current is usually regulated at $1\text{ }\mu\text{A K}^{-1}$.^[12] The IC sensors that regulate current proportional to temperature are particularly useful in measuring soil temperatures because they are insensitive to voltage drops over long lead wires. Any shielded and well-insulated twisted pair of conductors is sufficient for operation of the sensor hundreds of meters from the receiving meter. Current is calculated using Ohm's Law and the voltage drop across an inline resistor of known magnitude. Current-regulating sensors may be connected in parallel to measure a spatial average temperature.

Other soil temperature sensors take advantage of the sensitivity of electrical resistance of metals or semiconductors to temperature. Resistance temperature detectors (RTDs) are wire and metal film-type sensors that make accurate soil thermometers. Platinum RTDs are the most common. Resistances of platinum RTDs are usually $100\text{ }\Omega$ at 0°C , although new thin film deposition technology has led to creation of RTDs with resistances $>1\text{ k}\Omega$. The resistance of platinum increases almost

linearly with temperature, approximately 0.4% per $^\circ\text{C}$. Because of this linear relationship, RTDs may be connected in series and are used to measure an average soil temperature. The disadvantage to using RTDs as soil thermometers is that resistances of individual sensors are low enough that three- or four-conductor cables are required to account for the resistances of the lead wires.^[10]

Thermistors are also thermally sensitive resistors, but made from semiconductor materials. They have two distinct advantages over RTDs. First, their nominal resistance is greater so that only two conductors are usually required for lead wires. The second advantage is that their sensitivity to temperature is considerably greater. Meters are not required to measure with the precision necessary for RTDs. A disadvantage limiting the use of thermistors in averaging temperature is that their electrical resistance is usually a highly non-linear function of temperature.

Non-electric thermometers such as liquid-in-glass thermometers, dilatation thermometers, bimetallic thermometers, and manometric thermometers are sluggish and difficult to install in a manner that would minimize errors from heat conduction along the thermometer stem. In addition, thermometers that rely on thermal expansion as a measure of temperature are prone to serious errors in temperature measurement caused by external forces acting on the sensing portion of the device,^[13] such as forces present in soil prone to shrinking and swelling.

SOURCES OF ERROR

Spatial variability leads to uncertainty in measured soil temperature.^[8] The number of temperature sensors required to produce an average within a certain value of the mean must be determined from an *in situ* measure of variability.^[8] Fortunately, once the required number is known, then many thermocouples,^[8] IC temperature sensors,^[12] or RTDs sensors^[8] are easily connected in a configuration that provides an average temperature. By their nature, IRTs measure an average surface temperature integrated over an area that depends on the distance of the thermometer from the surface and its field of view.

Heat conduction down the lead wires or stem of the thermometer to the sensing element may lead to error. Thermal conductivity of copper, e.g., is two orders of magnitude greater than that of soil. To reduce conduction errors, a length of wire or portion of the thermometer stem should be buried along an isotherm of the temperature being measured. With electric thermometers, $0.2\text{--}0.5\text{ m}$ of wire buried along an isotherm is usually sufficient to reduce errors to within acceptable levels. Reducing the diameter of the lead wires near the sensor also will reduce heat conduction errors.

Lack of proper insulation and shielding of electric thermometers may also lead to serious errors. Insulation on sensors and cabling needs to be highly resistant to moisture.

Adhesive-lined heat-shrinkable tubing or resin-filled stainless steel tubing is a commonly used insulator for a sensor. To reduce the potential from electromagnetically induced noise, sensor cabling should be shielded and properly grounded. Except for the self-powered thermocouple, most electric temperature sensors are also susceptible to self-heating errors. To prevent errors caused by Joule heating the current should be kept below the self-heating limit imposed by the heat dissipation coefficient,^[10] but large enough to give adequate resolution on the meter.

INSTALLATION OF SUBSURFACE THERMOMETERS

Soil thermometers may be buried in disturbed soil or they may be installed on supports driven into the soil. Burying is most efficient when the thermometers are to be placed within about 0.15 m of the surface. Small diameter pipe has been used to house soil thermometers installed at greater depth.^[13] Metal pipe may be driven to considerable depth in hard soil, but its considerably different thermal properties affect the local temperature regime. PVC pipe is a better support for soil thermometers because its ability to transfer heat is nearly equal to that of dry soil. Insertion is relatively easy, provided a pilot hole is created. Electric sensors should be embedded and sealed so they are flush with the outside of the pipe. The lead wires should be located inside the tube and, to reduce the potential for errors from heat conduction along the lead wires, a section of the wires should be bunched inside the pipe at the same depth as the sensor. Wooden stakes with embedded thermometers also have been used for support. Like PVC, wood transfers about the same amount of heat in response to a temperature gradient as does soil.

Abstract

Tepetate is a vernacular Mexican term referring to a hardened land with various degrees of infertility. *Tepetates* are derived from volcanic material, mainly tuff. The scientific definition reserves the term *tepetate* for a hardened layer in soils formed from pyroclastic materials. In the central Valley of Mexico, these indurate layers are among the most striking pedological features. Two types have been recognized: the fragipan and the duripan type. The first one can be converted into soil after proper management to alleviate the social pressure for agricultural land.

TEPETATES: HARDENED VOLCANIC SOIL LAYERS

Tepetate is a vernacular Mexican term referring to a soil or hardened material with various degrees of infertility.^[1] Etymologically, *tepetate* derives from the Nahuatl term “tepetlatl” (“tetl” = stone and “petatl” = bed) which means “bed of stone.”^[2] However, in both folk and technical senses, *tepetate* has a wide semantic range of meanings.^[2,3] In the 16th century, the Nahuatl classification of earth materials included the *tepetate* as both a deductive class defined by slightly friable consistence “rock-like materials” and an inductive class of “arable soil.”^[2] It is speculated that the term *tepetate* was adopted to enclose two Nahuatl words: “tepetatl” and “tepetatlali,” used to differentiate between “bed of stone” inapt for agriculture and ameliorated “bed stone,” respectively. This explanation makes it easier to understand the ambiguity of the term. Studies on peasant soil classification make these terms equivalent to non-workable and workable land, respectively.^[4] Although the folk definition is widely used, a more modern scientific definition reserves the term *tepetate* for a hardened layer found in soils formed from pyroclastic materials.^[5,6] The main attribute of *tepetates* is their hardness when dry.

Hardened soil layers are not exclusive from Mexico. Similar formations can be found in Nicaragua, Salvador and Honduras,^[5,7,8] Ecuador,^[9] Chile,^[10] Peru,^[11] and Colombia^[12] under different names “talpetate,” “cangahua,” “tobas and ñadis,” and “sillares” (Table 1).

Pedologically, *tepetates* are surface or subsurface hardened layers derived from tuff,^[17] pyroclastic flows,^[5] or old volcanic ashes.^[18] *Tepetates* have been described as mineral “C” horizons little affected by pedogenetic processes, which correspond to an intermediate state of alteration of a vitric rhyolitic tuff.^[17,19] The main attribute of *tepetates* is its hardness, although there are big differences among different types. They vary in color from gray over yellow to reddish brown, as well as, in thickness and structure.

The best known *tepetates* in Mexico are located in the Valleys of Mexico and Tlaxcala, in the eastern and western slopes of the Sierra Nevada between 19°10' and 19°40' LN and 98°10' and 98°55' LW (Fig. 1).^[13,20,21]

Up to 10 layers of superimposed *tepetates* have been described in Central Mexico.^[21]

The first three series of these volcanic deposits (named T₁, T₂, and T₃) were dated between 10,000 and 40,000 years old.^[21] Peña and Zebrowski^[22] classified the *tepetates* of Central Mexico in accordance with two criteria: the stratigraphic series of origin and their consistency (similar to a fragipan or petrocalcic horizon). The fragipan-type *tepetates*, which are the ones that can be ameliorated for agricultural and forestry uses, were classified as *tepetates* types t₁, t₂, and t₃ with or without calcium carbonate.^[22]

This type of *tepetates* appears in different positions in the landscape, mainly in foothills and glacia, in the eastern and western slopes of the Sierra Nevada. Their characteristics differ in terms of the topographic position. Most of the *tepetates* located in foothills are of the fragipan type but

Table 1 Areas reported to have hardened layers of volcanic origin in different countries of Latin America.

Country	Name of the layer	Area (km ²)
Mexico ^a	Tepetate	30,700
Nicaragua ^b	Talpetate	2,500
El Salvador and Honduras ^c	Talpetate	Not reported
Ecuador ^d	Cangahua	3,000
Chile ^e	Ñadis y tobas	4,750 and not reported
Perú ^f	Sillares	10,000
Colombia ^g	Hardened volcanic formations	12,000–15,000

do not have all the characteristics required by the Soil Taxonomy to be classified as such, the reason for which they were called fragipan type (Table 2). In the “glacis,” located further down foothills, *tepetates* show calcareous coatings and are more like petrocalcic horizons.^[23]

The most outstanding physical properties of the fragipan-type *tepetates* are an average bulk density of 1.45 Mg m⁻³; total porosity near 40%, with a macroporosity often below 5%; a hydraulic conductivity of 0.3–0.5 mm hr⁻¹; a hardness to dry penetration below 20 kg cm⁻²; and texture from sandy clayey loam to silty clayey loam (with more than 25% clay).^[5,6,21] This kind of *tepetates* expands and gets friable when it is moist and

disintegrates when it is sunk in water. The physical properties, especially hardness and the low values of macroporosity in natural conditions, are serious limitations to farming (root development and water penetration) and favor surface erosion.^[24] Loss due to erosion amounts to 30 Mg ha⁻¹.

The fragipan-type *tepetates* are rich in bases, among which calcium, magnesium, and potassium prevail; they come from a mineral fraction rich in volcanic glasses and plagioclase highly susceptible to pedogenetic alteration. The cation exchange capacity ranges from 20 to 40 cmol kg⁻¹ of fine earth, due to the abundance of 2:1 clays; the percentage of base saturation is high. Reaction is slightly alkaline, pH 7.3–8.2, because of the presence of carbonates. These materials contain only traces of organic carbon (0.2–0.7%), nitrogen (0.04–0.07%), and soluble phosphorus (<3 ppm), which is one of its major chemical problems. These characteristics of this type of *tepetates* result in low fertility, so it is necessary to improve it before their rehabilitation for agricultural or forest use.^[24,25]

The material of origin of the fragipan-type *tepetates* is mainly made up of alkaline rhyolitic glasses, plagioclases, amphiboles, and pyroxenes of different sizes.^[19,21] Secondary minerals are a mixture of 1:1 and 2:1 clays, often interstratified with a 2:1 strong component of the beidellite type. Clays are very well oriented, which favor the cohesion of the fragipan-type *tepetates* and strengthens the compact nature of their matrix. This *tepetate* type presents “free” non-crystalline silica, accumulation of iron and manganese oxides, and occasionally calcite and only traces of allophane. Mineralogical properties explain only partly the behavior and characteristics of these materials.^[5,18,19]

The fragipan-type *tepetates* can be converted into soil after mechanically breaking up the hardened material^[24] to improve their physical conditions (pore space and water

Fig. 1 Localization of the *tepetates* in the landscape in Central Mexico.

Table 2 Similarities and differences between fragipan and *tepetates*.

Characteristic	Fragipan ^a	Tepetate
Layer thick	15 cm or more	6 cm or more
Pedogenesis	Evidence within the horizon or, at minimum, on the faces of structural units	Evidence within the horizon
Layer structure	Very coarse prismatic, columnar, or blocky structure of any grade; weak structure of any size; massive	Massive structure predominant and virtually no structural units, blocky structure of any grade in the t ₃ <i>tepetate</i>
Separations between structural units	Separations allow roots to enter, have an average spacing of 10 cm or more on the horizontal dimensions	Virtually no separations in the massive structure, but the spacing in the t ₃ <i>tepetate</i> can be around 10 cm
Diameter of air-dry fragments of the natural soil fabric	5–10 cm	Virtually no fragments when dry
Water behavior	More than 50% of the horizon slake when they are submerged in water; slowly or very slowly permeable to water	The <i>tepetate</i> slakes when submerged in water, slowly or very slowly permeable to water
Layer resistance	A firm or firmer rupture-resistance class in 60% or more of the volume, a brittle manner of failure at or near field capacity	Hard and very hard when dry and friable to very friable when moist
Roots	Virtually no roots	Virtually no roots
Organic matter content	Relatively low	Very low
Bulk density	High, relative to the horizons above it	Very high, relative to the horizons of the profile
Translocation of clay	Some evidences	Very frequent

^aNatural Resources Conservation Service. *Keys to Soil Taxonomy* (7th edition 1996 and 8th edition 1998).

retention capacity). Chemical and organic fertilizers must also be added to increase the available nitrogen and phosphorus as well as the organic matter content.^[26] *Tepetates* are very poor in the first two; however, their content of the other essential nutrients and clay, as well

as their cation exchange capacity, is similar to that shown by productive soils.^[26]

Manual incorporation of the fragipan-type *tepetates* to agricultural or forest activity began centuries ago. Mechanized methods were introduced by the mid-20th century. The ripped-up layer is 40–50 cm deep. Deep plowing is done when the *tepetate* is dry because fracturing of hard horizons is more complete than under moist conditions.^[27,28]

Ancient experiences gathered by local farmers and modern research experiences allow to propose a series of management practices for the rehabilitation of the *tepetates* of the fragipan type: 1) The *tepetate* layer must be broken at a minimum depth of 40 cm and fragments of a size between 3 and 5 mm must be left after the mechanical or manual preparation (actions leading to a very fine fragmentation, less than 2 mm, must be avoided, as well as a frequent tillage of the *tepetate*); 2) After tillage, organic matter must be added (an application of 40 Mg ha⁻¹ of farmyard manure had a 4-year residual effect); 3) Nitrogen and phosphorus fertilizers must be applied as a complementary practice to the addition of organic matter; rates to be applied must be based on the crop demand and the nutrient supply capacity of the recovered *tepetates*; nitrogen applications are recommended to be made in a fractional manner so as to improve their use and efficiency; 4) The crops showing the best responses in the first years of the *tepetate* incorporation are small-grain cereals such as wheat, barley, and oats and fodder crops such as vicia, trifoliums, and wild medicagos; good responses are obtained only as of the second or third cropping year for maize, beans, and broad beans, mainly planted in association; 5) In the initial phase of establishing a crop, especially if small-grain cereals, it is advisable to increase up to 50% the sowing density in order to have a better plant population; 6) The adoption of a crop rotation pattern containing legumes and Gramineae is recommended.

CONCLUSION

Tepetates are layers of hardened material that develop in profiles of lands formed from volcanic material in Mexico and other countries with volcanic influence and are object of particular scientific interest. Amelioration of the fragipan-type *tepetates* allows small farmers to have access to agricultural land and to obtain a means of support, reducing their migration toward populated areas, and at the same time slowing down erosion and desertification.

Abstract

Termites are abundant soil invertebrates in much of the tropics and subtropics. The physical effects of termites on soils range from the micromorphological to soil profile evolution and soil structure. There is evidence of enhancement of soil hydraulic conductivity and infiltration rates. Chemical effects include the promotion of litter decomposition, nutrient recycling, and the formation of stable pools of soil organic matter. In some landscapes, termite mounds act as foci for nutrient redistribution and contribute inorganic nitrogen following symbiotic fixation in the insect's gut. Termite mounds are sites of activity for diverse bacteria and fungi.

INTRODUCTION

Termites have a profound effect on soil properties, resulting both from their mound-building and gallery excavating activities and from their modes of feeding. Although other soil animals can affect soil properties, the importance of termites lies in their huge abundance and biomass in the tropics and subtropics and their unique associations with a diversity of microorganisms. Contrary to common assumptions, most termite species are beneficial to plant growth: they promote organic matter decomposition and nutrient cycling and reduce erosion through a strong influence on soil physical, chemical, and biological processes. They also have long-term effects on soil development and the character of landscapes. For a modern synthesis of termite biology refer Abe et al.,^[1] and for a review of economic impact and control methods, see Pearce.^[2]

TYPES

Termites are eusocial, polymorphic insects (order Isoptera) with generally cryptic behavior. They live in large family groups that are composed of reproductive forms (sometimes winged), together with numerous sterile soldiers and workers. Sometimes known inaccurately as “white ants,” termites are derived forms of cockroach which depend on mutualistic intestinal bacteria and, in some higher forms, externally cultivated basidiomycete fungi, for assistance with energy metabolism and the provision of nitrogen (N). Some termites also contain populations of flagellate protozoans in the hindgut, a number of which have the ability to degrade cellulose and other plant polysaccharides. Termites are the only social insects with a true soldier caste having no role other than to

defend the colony. More than 2300 species have been described in 270 genera and 6 families. Most of these are beneficial inhabitants of tropical and subtropical forests, savannas, and rangelands. A small number of relatively primitive species, loosely termed “drywood termites,” “dampwood termites,” and “subterranean termites,” are able to colonize and/or consume timber used for buildings, furniture, transmission poles, and fencing; such pest species are inadvertently distributed by humans and become pantropical, with one or two species extending their range to include cities in temperate zones. Other species are agricultural or silvicultural pests, especially where non-indigenous crops are introduced or where land is cleared of natural plant detritus prior to planting or not fertilized with mulch.^[3] The large majority of termite species are not pests and can be grouped heuristically into four broad functional categories based on their diets: grass-feeders, litter-feeders, wood-feeders, and soil-feeders. The last group dominate lowland tropical forests and the wetter savannas; grass-feeders and wood-feeders become relatively more common as aridity increases; almost all termite species are associated with the soil in some way, using it as either a habitat, a resource, or both. Under most global change scenarios, non-soil-feeding species are likely to become more dominant, but overall termite biomass may decline.^[4,5]

HABITAT

Termite diversity is strongly influenced by latitude (the numbers of naturally occurring taxa declining steadily north and south of the Equator) and by rainfall (species richness and abundance generally increasing with greater rainfall at the same latitude). Constructions made by

termites include: numerous galleries tunnelled through wood and soil; underground chambers containing the queen, king, larval nurseries, and (in the subfamily *Macrotermitinae*) symbiotic fungus gardens; runways attached to the sides of trees, decaying wood, and buildings; soil sheeting covering the surface of the ground; and arboreal or epigeal (i.e., emerging from the surface) mound nests with a complex internal structure. Materials utilized, manufactured, or translocated by termites include: surface soil; subsoil; compacted feces; and carton (a lightweight organic-rich mixture of partially digested cellulose, saliva, and soil). Epigeal mounds can attain a height of more than 7 m but most are much smaller (Fig. 1). Many termites live underground with little indication of their presence at the soil surface. A large number of species are not primary mound builders, either living entirely in diffuse subterranean gallery networks or becoming established in pockets within the mounds of other species as secondary occupants.^[6,7] Arboreal species are often conspicuous, but less important in biomass terms than subterranean forms, except where inundation is frequent. All termites are detritivores, consuming and digesting (in different species) a wide range of freshly dead or decaying plant material including dry grass, leaf litter, sound wood, decaying wood, dung, and humus-rich soil. Lichen and living roots may also be eaten, often without damage to plants. Termite abundance varies from less than 50 individuals m⁻² in arid savannas to more than 7000 m⁻² in some African forests. The corresponding biomass densities range from negligible to more than 100 g live weight m⁻² in exceptional cases. In the tropics as a whole, they are estimated to constitute 10% of all animal biomass (up to 95% of soil insect biomass) and to impact C mineralization (decomposition) to roughly the same extent as all mammalian herbivores and natural fires. Overall, they contribute about 2% of the CO₂ flux to the atmosphere from

all terrestrial sources. Earlier concerns about the possible role of CH₄ production by termites in global warming have now been shown to be unfounded.^[8]

EFFECTS ON SOILS

Through their activities as decomposers and constructors, termites have important roles in the genesis, morphology, and properties of soils throughout the tropics and subtropics.^[5] They also fix N on a significant scale, through mutualistic gut bacteria, and may be the primary providers of this nutrient in many soils and food chains, with termite mounds serving as foci for nutrient redistribution in some landscapes. It is highly probable that termites function as keystone species in ecosystems (creating niche opportunities for a large number of other organisms) and as ecosystem engineers (mediating biological function and maintaining soil structure, fertility and stability). Evidence is accumulating that termites (with earthworms) strongly affect C mineralization, the establishment of stable pools of complex organic material, N fixation, and denitrification. As a consequence, long-term exclusion or poisoning of termites changes the character of plant communities as well as adversely affecting soil porosity, aeration, water-holding capacity, hydraulic conductivity, infiltration rates, and drainage.^[4,7]

The physical effects of termites on soils range from micromorphological to soil profile evolution and structure.^[7] Soil translocation is a major consequence of nest building, and the construction of foraging runways at the soil surface or above the ground. Estimates of the quantities moved vary but may approach 5 ton ha⁻¹ year⁻¹ in some systems; over thousands of years, these activities strongly influence soil profile development, especially lateritic profiles and ferrisols.^[7,9,10] Micromorphological analysis of tropical soils frequently shows the presence of small (<1 mm pellets of biological origin, thought to be produced either by termite fecal deposits or the mixing of soil with termite saliva using the mandibles. The pellets, which may comprise up to 20% of the soil matrix, have a major influence on microporosity, moisture storage capacity, and infiltration rate. Subterranean chambers and galleries are also a conspicuous feature of soil profiles, almost universally detectable in soil cores and accounting for up to 2% of total soil volume, with effects on both infiltration rates and drainage. The behavior of termites in repacking soil particles, augmented with organic material derived from salivary and fecal products, while constructing mounds and galleries, is a key activity.^[7] It can be shown to affect bulk density (this is increased, restricting seed lodgement and growth), structural stability (this is increased when termites construct mounds that are highly organic, e.g., containing hemicellulose or glycoprotein), and hydraulic conductivity (both conductivity and flow rates are reduced if termite galleries are reduced and, correspondingly, increased after mulching that attracts additional termite foraging).

Table 1 Soil properties significantly affected by termites.

Soil property	References
Soil profile development	[7,10–12]
Bulk density	[7]
Hydraulic conductivity/infiltration rates	[7,13]
Soil chemical properties	[5]
Organic matter decomposition	[7]

The chemical properties of soils depend primarily on their parent materials but with additional influence from climate, vegetation cover, and the activities of soil organisms. A notable contribution of termites is the incorporation of cation-rich clay subsoils, together with organic-rich fecal and salivary materials, into constructions.^[5,7,9] In many cases, when these are subsequently eroded, the surface soil becomes enriched in Ca, magnesium, sodium, potassium, together with organic N, phosphorous, and interstratified clay minerals. Several studies have shown that the inorganic nitrogen concentrations of mound soil or of soil reworked by termites are higher than adjacent soils that are unaffected by termites; this nitrogen apparently originates from symbiotic fixation within the termite gut. Leaching of such nitrogen represents a short-term redistribution and can be a significant input to the soil pool that is immediately available to plants.^[7] Non-mutualistic bacteria and fungi may also be present in larger numbers in mound soils, and the assessments of their activities suggest a vigorous metabolism which includes (in separate species) cellulose degradation, nitrification, and denitrification. Many evidences indicate that the presence of termite mounds promotes the accumulation of plant biomass on or around the structure.^[3,7] In semiarid systems, mulching of the soil to promote termite activity can lead to significant improvements in plant cover, plant species number, biomass production, and rainfall use efficiency. A summary of the effects of termites on soils is presented in [Table 1](#).

CONCLUSION

Termites are abundant soil invertebrates in much of the tropics and subtropics. The physical effects of termites on soils range from the micromorphological to soil profile evolution and soil structure. There is evidence of enhancement of soil hydraulic conductivity and infiltration rates. Chemical effects include the promotion of litter decomposition, nutrient recycling, and the formation of stable pools of soil organic matter. In some landscapes, termite mounds

act as foci for nutrient redistribution and contribute inorganic nitrogen following symbiotic fixation in the insect's gut. Termite mounds are sites of activity for diverse bacteria and fungi.

Abstract

Fertile dark-colored soils in the Amazon (anthropogenic dark earths or *terra preta de Indio*) have been attached to historic anthropogenic soil modification through black carbon and other organic amendments from both agricultural and waste management activities of ancient Amazonian natives. This hypothesis was supported by the presence of artifacts (e.g., ceramic pieces) located within these soils and by the assumption that these deposits were unique to the Amazon region. This model of *terra preta* development has fueled the renaissance into recreating bolstered soil fertility through intentional black carbon additions.

Fertile dark-colored soils in the Amazon [anthropogenic dark earths or *terra preta de Indio* (TPI)] have been attached to historic anthropogenic soil modification through black carbon and other organic amendments from both agricultural and waste management activities of ancient Amazonian natives.^[1,2] This hypothesis was supported by the presence of artifacts (e.g., ceramic pieces) located within these soils^[3] and by the assumption that these deposits were unique to the Amazon region.^[4] This model of *terra preta* development has fueled the renaissance into recreating bolstered soil fertility through intentional black carbon additions.^[5] However, improving soil is an intricate process involving not solely the addition of an individual chemical component but also the interactions between all of the following soil-forming factors: climate, topography, parent material, organisms (vegetation), and time.^[6] This entry expands on the observations of a new possible interaction between fire, time, and iron mineralogy that might play a significant role in the development of these TPI soils.

Terra preta soils are chemically distinguished by the presence of Ca^{+2} , phosphorus (P), Mg^{+2} , high base

saturation, and carbon contents and by the absence of extractable Al^{+3} compared to surrounding soils and geologic materials.^[7,8] Due to the contrasting soil chemistries of surrounding and deeper layered soils, the presence of calcium, P, and the pottery fragments has typically provided an evidence for anthropogenic influences in the development.^[9] However, the exact soil formation history is not fully elucidated. The most prominent feature of the *terra preta* is the dark brown to black coloration (e.g., Munsell® colors 10YR3/1; 5YR2/2), which is in stark contrast to the yellow to orange coloration of the surrounding geologically derived soil (e.g., 5YR5/8).^[3,8,9] Despite the fact that there is evidence of anthropogenic activity in some of the *terra preta* soils,^[4] not all of the *terra preta* soils have this characteristic. Based on the observations of other soils in Brazil^[11] and other continents,^[10] our suggestion here is that the *terra preta* (and other black carbon rich) soils are derived from fire residuals as a soil parent material and not solely linked to anthropogenic alteration.

In Southern Brazil (Monte Alto, São Paulo state; 21.3°S 48.5°W, elevation 700 m), distant from the Amazonian region, there are other examples of dark fertile soils in

Fig. 1 Illustrations of location of the soil profile in Humaitá Town (AM Oxi),^[6,11] TransAmazonica Highway—180 km (TPI),^[6,11] and Monte Alto Town (MA Fire) in Brazil, the carbon-rich soil material comprising the first 15–30 cm of soil at the Monte Alto site (white circle in the soil profile MA Fire) at a topographic summit, in particular the movement of the black-colored soil by erosion down the vertical face of the exposed outcrop, the thick (>50 cm) fertile soil located in the depositional valley, and the charred tree stumps and remaining forest debris that clearly show the evidence of fire activity at the site.

tropical climates. We investigated one of these sites that possess a history of natural fires which occurs during drought periods (Fig. 1). This site is on a topographic high, void of any potential agricultural amendment practices. The residuals from this reoccurring natural fire activity have produced a veneer surface of carbon-rich soil with contrasting soil chemistries compared to the surrounding and deeper layer geological derived soil. This new carbon-rich soil, derived from parent material with very low or zero magnetic expression, ranges in depth from 10–35 cm in the topographic high areas to >50 cm in the base of the valley, in Southern Brazil. This soil possesses elevated concentrations of P, Ca^{+2} , and Mg^{+2} , high base saturation levels, and elevated soil carbon, when compared to surrounding soils, the typical Southern Brazilian or Amazonian Oxisols (AM Oxi; Fig. 1). Hence, these soil properties of Monte Alto (MA) fire site shared with the *terra preta* soils in the Amazon (TPI compared to MA Fire) are in stark contrast to native soil properties (AM Oxi). In addition, the iron oxides of maghemite and magnetite are also present confirming the occurrence of fire,^[12] which is corroborated by the visible charring of the trunks and forest debris at the Monte Alto site. The valleys in Monte Alto area contain fertile black earth soils (Mollisols; Fig. 1). Most striking is the similarity in soil chemistries of these newly formed soils from fire residues and the *terra preta* soils (Fig. 2), which are also shared with soils in the Monte Alto valley. Total organic carbon and P contents in shallow soil layers in TPI and MA Fire sites are with much higher contents than the typical Oxisols. The same applies for bases, aluminum (Al) + hydrogen (H), Ca^{+2} , and other elements, which have higher contents at shallower layers (lighter colors) compared to the deeper soil layers (darker colors) in MA Fire and TPI sites.

The magnetic susceptibility (MS) values (also presented in Fig. 2 and Table 1) suggest a higher presence of

ferromagnetic crystals (like maghemite) in MA Fire and TPI soils. The geologic parental material at the MA Fire is a carbonated rock, with low iron content and low MS value of $22 \times 10^{-8} \text{ m}^3 \text{ kg}^{-1}$. In this environment, carbon in soil organic matter is hypothesized to be preserved due to high pH values. But with fire occurring, soil carbon could additionally form complexes with ferromagnetic iron minerals. MS values are higher in MA Fire ($97 \times 10^{-8} \text{ m}^3 \text{ kg}^{-1}$), as ferromagnetic iron minerals formed by fire are leached, accumulating between the fire residues on surface and the rock. However, the overall presence of MS in the soil profiles also suggests substantial mixing in these soils, which could result as a consequence of fire-impacted areas possessing a high erosion potential and a propensity for landslides.^[13,14] This infrequent but massive movement of soil as being the major contribution of dissolved sediment in tributary rivers in the Amazon has been confirmed.^[14] The higher MS value of AM Oxi ($70 \times 10^{-8} \text{ m}^3 \text{ kg}^{-1}$) is a result of the higher iron content of parent material, different from the MS value of MA Fire, but both have their MS increased due to this interaction between soil carbon, iron, fire, and climate.

These data support a conclusion that both the Amazonian *terra preta* and Monte Alto soils have resulted from similar parent materials, in other words, fire residuals from natural vegetation fires. Natural wildfires do occur in tropical rain forests, with typical concentration around the transitional edges of the forest (cerrado or savanna), as well as topographic highs. These fires are triggered by lightning during seasonal water stress, which can be assumed to have occurred in the geologic past, in both the mainland of Brazil and the Amazon.^[13–15]

The fundamental assertion here is that these *terra preta* soils originated directly from this fire residual parent material. The use of these naturally fire-cleared areas by the past Amazonian natives would also make logistical

Fig. 2 Chemical data from the average of *terra preta* soils in the Amazon (TPI),^[16] MA Fire,^[17] and native Amazonian Valley (AM Oxi) illustrating the distinct chemical differences of both the MA Fire and TPI soils compared to the typical oxisol soil for organic carbon content, P, Al + H, base saturation, magnesium, calcium, and MS. sense, because nature strives for the path of least resistance. Following these fire events, the soils are also highly susceptible to erosion by massive debris flows (landslides)

during storm events. This overall mechanism agrees with the data collected from dissolved sediments in the upper Amazonian headwaters,^[14] confirming that the majority

Table 1 Surface (0–20 cm) and deeper soil data (as in Fig. 2) from the average of *terra preta* soils in the Amazon (TPI),^[16] MA Fire,^[17] and native Amazonian Valley (AM Oxi) illustrating the distinct chemical differences of both the MA Fire and TPI soils compared to the typical oxisol soil for organic carbon content, P, Al + H, base saturation, magnesium, calcium, and MS.

Organic carbon (g kg ⁻¹)			P (g kg ⁻¹)		Al + H (cmol kg ⁻¹)	
Site	0–20 cm	Deeper	0–20 cm	Deeper	0–20 cm	Deeper
TPI	53.18	17.78	63.25	10.44	7.6	4.05

MA Fire (rock)	22					
AM Oxi	70.3					

of sediment enters in very brief but substantial loading events that are infrequent and not solely linked to seasonal patterns.

In the classic pedogenic model, Jenny^[18] equated climate, topography, parent material, organisms (vegetation), and time as the factors determining soil formation, with parent material being thought of as physical and chemical transformation of geologic formations. However, our new observations in Southern Brazil coupled with other reports of other *terra preta*-like soils in other continents^[10] support the conclusion that these black earth soils should be considered as derived from fire residual parent materials only and not from the modification of existing geologic soils, and ferromagnetic minerals could be used as a pedogenic indicator of soil evolution in the genesis of TPI soils or any other soils formed by fire residues. This new parent material classification would provide harmony and clearer linkages between other localized occurrences of increased black carbon soils present across all of Brazil as well as on other continents.

CONCLUSION

Our results suggest a new vision on the evolution and formation of soils derived from fire, which have broader evidences from other sites but have similar aspects such as iron content in soil plus fires. The MS has the potential to be used as an indicator of the quality and evolution of soils formed in the presence of fire. The understanding of the formation of iron oxides and their changes induced by fire in those natural environments could assist in understanding the potential soil carbon accumulation of those sites.

Terra Preta de Indio

Johannes Lehmann

Department of Crop and Soil Science, Cornell University, Ithaca, New York, U.S.A.

Abstract

Terra preta soils are fertile and carbon (C)-rich soils found throughout Amazonia. These soils have been created by Amerindian populations before the arrival of Europeans. The key to their unique properties is the high charcoal (also called black C or biochar) contents that have great stability and ability to improve both chemical and biological properties of soils. Important lessons can be learned from terra preta about the development of civilization in the Amazon, basic functioning of soils, C sequestration, and sustainable land use.

INTRODUCTION

Terra preta de indio soils, also called Amazonian dark earths,^[1] are found throughout most of the Amazon Basin. Terra preta means “black earth” in Portuguese, and their dark color makes them distinctly different from the surrounding soils. The interest in terra preta arises from their unique properties, namely their high soil fertility and production potential as well as high carbon (C) contents, which have implications both for the study of the development of civilization in the Amazon and for modern sustainable land use.^[1] Terra preta soils were described in the scientific literature for the first time by Charles F. Hartt,^[2] although in-depth scientific research documenting its unique properties started only in the middle of the 20th century. This entry gives a brief overview of the properties, origin, and distribution of terra preta soils.

PROPERTIES OF TERRA PRETA DE INDIO

The dark color of terra preta results from large amounts of both organic matter and charcoal (also called “black C” in biogeochemical literature and “biochar” when linked to purposeful soil management).^[3] The source of the charcoal can be linked to occupation by Amerindian populations, and the charcoal is therefore several hundred to a few thousand years old as seen from the ¹⁴C dates obtained from charcoal fragments (Fig. 1). The high concentrations of charcoal in terra preta are also a testament to its high stability against mineralization. Indeed, the organic matter in terra preta is highly resistant against microbial decay and that recalcitrance barely changes over millennial timescales.^[4]

Charcoal is the reason for the high cation exchange capacity of terra preta soils^[5] with high concentrations of plant-available nutrients and often higher pH than that

of the surrounding soils^[1] (Fig. 1). The elevated nutrient concentrations are also a result of burial activities, food preparation and waste (especially phosphorus (P)- and calcium (Ca)-rich fish waste), animal and possible human excrements, debris of housing materials such as straw or palm leaves, and various other activities (dyes, oils, fiber from palms and bark, etc.).^[6] The characteristics are the often very high P and Ca contents in terra preta, but also magnesium, manganese, zinc, and copper and to a lesser extent nitrogen and potassium contents are typically elevated.^[1]

The chemical properties and chiefly the high charcoal contents also change the environment for biological processes in terra preta. For example, the diversity of microbial populations commonly shows a greater species richness.^[7] The mechanisms by which abundance and ecology of soil biota are affected are not sufficiently clear. It is plausible that better nutrient availability or higher pH values enhance the activity and reproduction of microorganisms and alter species composition. Observations about the interactions between charcoal and microorganisms also suggest specific effects of charcoal on soil ecology.^[8] In many instances, terra preta soils contain large amounts of pottery shards, indicating past occupation that may also modify soil properties.

THE ORIGIN OF TERRA PRETA DE INDIO

The origin of terra preta has been the subject of much debate.^[9] While early reports speculate about volcanic ash deposits or sedimentation processes, it is by now accepted that terra preta soils were created by human activity^[10] and are therefore aptly called “terra preta de indio”—black earth made by Amerindians. The main arguments for the human origin are the abundance of artifacts in combination with high charcoal and P contents in terra preta soils (Fig. 1) and similarity in mineralogy of clays between terra preta

Fig. 1 Physical and chemical properties of a terra preta profile and the adjacent soil near Lago Grande, Manaus, Brazil (location and chemical analyses and uncalibrated ^{14}C dates of charcoal; nd: not determined).

Source: From Liang, Lehmann, et al.,^[4] Liang, Lehmann, et al.,^[5] and Neves, Petersen, et al.^[6]

and the surrounding soils.^[4] While some uncertainty will likely remain as to whether terra preta soils were created intentionally as part of soil management for agriculture or they are a by-product of habitation, it is certain that their occurrence is inextricably linked to Amazonian civilizations before the arrival of the Europeans. Amazonia was densely populated around the year 1492, being home to sophisticated populations who lived in urban clusters.^[11] Given that shifting cultivation is an unlikely land use system before steel axes made frequent slashing of trees possible,^[12] a purposeful soil management is a more likely explanation for the high and sustained crop productivity needed to feed larger urban centers. Terra preta soils were created between 500 and 8000 years B.P.,^[6] but not to any significant extent after the arrival of the first European explorers in 1541. They are therefore remnants of ancient civilizations in the Amazon Basin.

DISTRIBUTION OF TERRA PRETA DE INDIO

Terra preta soils are widely distributed in the Amazon Basin, but their occurrence is poorly documented. It appears that terra preta soils are most widespread in the Central Amazon between Manaus and Santarém (Fig. 2). Most terra preta sites have been mapped close to major streams that provide transportation by boat and food through fishing activities. Sites are located preferably on bluffs, which improve control over the surrounding area in case of warfare.^[9] Some studies, however, find more than half the sites to be far from any major river.^[10] As surveys

extend further into remote areas and away from waterways, the available information may be refined.

Terra preta occurs on all major soil types,^[13] indicating that physical and chemical attributes of the soil prior to occupation did not play a major role in their distribution. The enrichment with organic C and nutrients typically reaches much deeper in terra preta than in the surrounding soils (Fig. 1). In an assessment of about 190 soils, 57% of the profiles had an A horizon that reached to a depth of between 0.2 and 0.6 m, which is significantly deeper than those of adjacent forest soils with about 0.1–0.15 m.^[13] In some cases, the dark coloration reaches to depths of more than 2 m.

Some sites show vast expanse of several hundred hectares, such as the terra preta underlying the city of Santarém. But most documented sites are small with sizes of less than 2 ha.^[13] The challenge in these assessments lies in the identification of what constitutes a terra preta, as the boundaries are ill-defined, and soil changes are often difficult to detect in the field without chemical analyses.

Another factor is that soil changes may occur gradually from terra preta to uninfluenced soils and that such transitional soils may deserve their own category. These so-called “terra mulatta” (Portuguese for “brown earth”) have been described as a distinct soil type^[14] and often surround terra preta. The area of terra mulatta can be expansive and is estimated to exceed the area occupied by terra preta (Fig. 3).

The chemical properties of terra preta and terra mulatta are different. Typically, terra preta soils are darker than terra

Fig. 2 Distribution of terra preta de índio (white dots) and major cities (black triangles) in the Central and Eastern Amazon region.
Source: From Lehmann, Kern, et al.,^[1] Kern, D'Aquino, et al.,^[13] and background map from NASA Images at www.nasaimages.org.

mulatta, even though organic C contents are often similar.^[15] Terra mulatta have lower nutrient availability, principally of P and Ca, than terra preta,^[15] and do not contain artifacts such as pottery shards. Therefore, such terra mulatta are not middens but may actually constitute agricultural areas^[15] that were generated through charring both during field establishment and on an annual basis using crop residues.

Terra preta and terra mulatta are archaeologically important testaments to the culture of ancient civilizations in the Amazon Basin. They provide information about the way Amerindian populations lived and utilized their environment, sustaining seemingly large and complex societies. Also the mere existence of C-rich and fertile Terra preta de índio several millennia after their creation demonstrates how soils function and suggests the ways for improving soil

sustainability. Principally, the discovery of the role of charcoal as a key ingredient in terra preta has led to the development of biochar soil management to improve soil fertility and mitigate global warming through long-term C sequestration.^[16] Such modern biochar management affords the possibility of withdrawing carbon dioxide from the atmosphere while achieving sustainable soil improvement.

Abstract

As an agronomic tool, soil testing represents an index of measurement of nutrient availability. Soil testing, combined with other agronomic information, helps determine the best way to manage nutrients. There is an interest to use soil testing to determine the pollution of surface water and groundwater from fertilizer/waste material application. However, to identify the potential impact of pollutants, a comprehensive approach should be taken on the environment and soil testing. This entry describes the steps in soil testing.

INTRODUCTION

Soil testing is generally defined as any chemical and physical measurement that is made on a soil. The term soil testing may be a rapid chemical analysis to assess the plant-available nutrient status, salinity, and elemental toxicity of a soil or may represent a program that includes interpretations, evaluations, and fertilizer and amendment recommendations based on the results of chemical analysis.^[1,2] As an agronomic tool, soil testing represents an index of measurement of nutrient availability. The objectives of soil testing are as follows: 1) to provide an index of nutrient supply in a soil; 2) to predict the probability of obtaining a profitable response to fertilizers and/or lime; 3) to provide a basis for recommendations on the amount of fertilizer and/or lime to apply; and 4) to evaluate the fertility status of soils by the use of soil test summaries.^[3] Soil testing, combined with other agronomic information, helps determine the best way to manage nutrients. There is an interest to use soil testing to determine the pollution of surface water and groundwater from fertilizer/waste material application. However, to identify the potential impact of pollutants, a comprehensive approach should be taken on the environment and soil testing. Different steps in soil testing follow.

SOIL SAMPLING

Soils are heterogeneous (both horizontally and vertically), and it is, therefore, important that the sample collected for analysis be representative of the field.^[1] Errors in soil sampling fall into the following three general categories: sampling error, selection error, and measurement error. Sampling error is caused by the inherent variation and can be avoided by including the total population in the sample. Selection error arises from any tendency to select some units of the population with greater or lesser probability than was

intended. Measurement error is caused by the failure of the observed measurement to be true to value for the unit. It includes both the random errors of measurement and biases.

The most critical aspect of soil testing is obtaining a soil sample that is representative of the site.^[3] Statistical concepts determine which of the following three commonly used sampling strategies are used: 1) simple random sampling; 2) stratified random sampling; and 3) systematic or grid sampling. Other important factors to consider are the depth of sampling, degree of field variability, number of cores needed to constitute a single composite sample, tools used to collect soil sample cores, type of containers, frequency of sampling, and the effect of season on sample collection.^[4]

PREPARATION OF SOIL SAMPLES FOR LABORATORY ANALYSIS

Sample preparation is critical in obtaining accurate results.^[4] The field-moist soil samples must be dried promptly to minimize microbial activity. The drying temperature can have a significant effect on the physiochemical properties of soils. Generally, the soils are air-dried. If an air-circulating oven is used to speed up the process, temperature should not exceed 38°C. The soils are ground to 2 mm size for routine analysis. For certain analyses, the samples need to be ground further to 1 mm size or finer.

APPARATUS FOR SOIL ANALYSIS

A soil laboratory would contain the following apparatus: soil grinder, sieves, auto-dispensers, funnel racks, titrator, time-controlled stirrer, time-controlled shaker, and balances. It would also have ovens, muffle furnace, pH meter, conductivity meter, sulfur analyzer, nitrogen analyzer, continuous flow analyzer (air-segmented and non-segmented

stream instruments), ultraviolet-visible spectrophotometer, ion chromatograph, atomic absorption spectrophotometer, flame emission spectrophotometer, and X-ray fluorescence spectrophotometer. Finally, the laboratory would have a potentiometric instrument; inductively coupled plasma atomic emission spectrophotometer; and glassware, plasticware, and other apparatus generally considered common to soil analysis laboratories. Computers, integral parts of modern laboratory instruments, are used for setting instrument parameters, controlling the operation of the instruments, and data capture and storage.

METHODS OF SOIL TESTING

Chemical soil tests are designed to estimate the amounts of plant nutrients available for plant growth. Different reagents are being used to extract different nutrients as listed in Table 1 and analyzed using the instruments given in the previous section. Apart from nutrient contents, loss on ignition or a potassium dichromate wet oxidation procedure routinely determines organic matter. Soil texture is determined by sedimentation procedure in the laboratory and hand texturing method in the field.^[4] Soil pH is determined in a soil–water slurry of 1:1 or 1:2 or in a soil slurry

of 0.01 M CaCl₂ or 1 M KCl. Exchangeable acidity is determined by using the barium chloride–triethanolamine (TEA) extractant buffered to pH 8.2. The Adams–Evans buffer^[5] and the Shoemaker, Mclean, and Pratt buffer^[6] methods are used to determine the lime requirements of coarse-textured and fine-textured soils, respectively.

Fixed extraction ratios (e.g., 1:2 and 1:5) and saturation extract methods are used for the measurement of electrical conductivity. However, an estimation of the soluble salt content of soils is carried out using a 1:2 soil/water ratio. The sodium adsorption ratio is an useful index of soil sodicity based on the ratio of basic cations, which can be calculated from chemical analysis of the soil extract.^[4]

Soil structure, air porosity, water desorption characteristics, bulk density, saturated hydraulic conductivity, and infiltration rate are measured *in situ* and in laboratory.^[4]

CORRELATION AND CALIBRATION

Correlation is the process of determining whether there is a relationship between the soil test results and the plant uptake of a nutrient or yield. A soil test for a given nutrient has historically involved three steps: 1) selecting an extractant; 2) correlating the amount of nutrient extracted with the amount taken up by the plant; and 3) calibrating the test values with crop yields. Nutrients extracted in soil testing procedures are frequently referred to as “available nutrients.” The Glossary of Soil Science Terms^[7] defines available nutrients as the amount of soil nutrient in chemical forms accessible to plant roots or compounds likely to be convertible to such forms during the growing season. For the purpose of soil testing correlation, the rate at which a nutrient is taken up by the plant becomes more important than the amount of the available nutrient. Thus, the correlation of estimated nutrient uptake based on soil testing and other pertinent factors with total uptake by plant seems to be a logical approach.^[8] This can be accomplished by greenhouse experiments and field trials, along with the use of empirical and mechanistic modeling approaches.

Calibration is the process of determining the probability of getting a growth response to applied nutrients. Calibration of a soil test is basic to a good soil testing program. Soil test extractants were designed to rapidly and accurately assess the available nutrient status and/or elemental toxicity in soils. They were also designed to provide a quantitative basis for recommendations of the rates of plant nutrients that should be added as fertilizers, manures, or other materials to economically achieve optimum yield. A properly calibrated soil test should provide information on the degree of deficiency or sufficiency of an element and identify how much of the element should be applied if it is deficient. There are additional criteria of a successful soil test. It should be easy to perform to ensure rapid turnaround time, cost-effective to promote wide usage, and reproducible.

Table 1 Commonly used extractants for plant nutrients.

Soil nutrient	Extractant
NO ₃ -N	2.0 M KCl
NH ₄ -N	2.0 M KCl
P	0.03 M NH ₄ F + 0.025 M HCl (Bray-P1) 0.05 M HCl + 0.0125 M H ₂ SO ₄ (Mehlich-1) 0.5 M NaHCO ₃ , pH 8.5 (Olsen-P) 0.2 M Acetic acid (CH ₃ COOH) + 0.25 M NH ₄ NO ₃ + 0.015 M NH ₄ F + 0.013 M HNO ₃ + 0.001 M EDTA (ethylene diamine tetraacetic acid; Mehlich 3) 0.25 M CH ₃ COOH + 0.15 M NH ₄ F (Kelowna)
Cation exchange capacity (Ca, Mg, K, and Na)	1.0 M ammonium acetate (NH ₄ C ₂ H ₃ O ₂), pH 7.0
S	Ca (H ₂ PO ₄) ₂ , containing 500 mg/L P 0.01 M CaCl ₂ 0.25 M CH ₃ COOH + 0.15 M NH ₄ F (Kelowna)

INTERPRETATION AND RECOMMENDATIONS

Soil testing interpretation is the process by which one assesses the fertility status of a field based upon a set of known factors. It involves an evaluation of chemical test results in terms of basic soil–plant relationship phenomena. More complex interpretation may include consideration of factors such as the crop to be grown, yield goal, individual soil characteristics, climate, tillage system, and environmental quality.^[9] Many fertilizer recommendations are made using interpretation of both the concepts and designs to fertilize the soil rather than the plants. Recommendations based on basic cation saturation ratio are designed to alter the existing ratio to achieve the ideal K/Ca/Mg ratio, regardless of the existing and potential yield levels. The recommendations are based on soil test results and other agronomic conditions.^[9]

QUALITY CONTROL PROCEDURES FOR SOIL ANALYSIS

The quality of soil test results is evaluated on the basis of the following two components: bias and precision. Bias refers to the deviation of analytical result from the true value and measures accuracy of the result. Precision refers to the reproducibility of a given test value. A primary means to evaluating soil test quality procedures, as well as performance, is through a comparison of laboratories performing the same test procedure on the same soil. The use of appropriate reference soils to assess, monitor, maintain, and ensure the accuracy of analytical results should be part of a soil testing procedure. Incorporation of reference materials is one cost-effective facet of a data quality program to ensure the accuracy of analytical results.^[4]

It is vital that laboratories monitor and document the quality of their analytical results on a regular basis. For this purpose, many laboratories participate in proficiency testing programs. The Soil and Plant Analysis Council, Inc. (formerly the Council on Soil Testing and Plant Analysis) was founded in 1969 to address the issues of uniformity in the analytical procedures and fertilizer recommendations.^[10] The AOAC International is an association of scientists and organizations devoted to promoting methods validation and quality measurements in the analytical sciences. In 1990, the Soil Science Society of America and the AOAC International established a joint committee to conduct validation studies for methods of soil analysis. The first validation was for soil pH methods.^[11]

FUTURE OF SOIL TESTING

The future of soil testing is bright. There will be greater automation in the laboratory and wider use of multielement extractants. The search for better methods to evaluate bio-availability of elements in soils will continue to be an important concern and will affect both the agronomic and analytical aspects of soil testing. No unusually drastic change is anticipated concerning laboratory procedures, but there is an expected change in the future use of soil tests, as less of a diagnostic procedure and more of a monitoring one.

Abstract

Soil texture is the consistency of a moist soil felt between the fingers and is associated with its particle size distribution. Texture is a fundamental property that affects many of the physical and chemical properties and behavior of the soil, such as the soil water and nutrient holding capacities, hydraulic conductivity, and resistance to cultivation. Soil texture is affected by clay content and type, silt and organic matter contents of the soil as well as the ion composition on the surfaces of the clay fraction.

INTRODUCTION

Besides color, one of the principal descriptors of a mineral soil (i.e., one with less than 10% organic matter content) is its texture, which is well correlated with the particle size distribution of the fine earth fraction (<2 mm fraction). The distribution of particle size is conveniently partitioned by particle size analysis (PSA) into subfractions of sand, silt, and clay, the proportions of which will have a dominant influence on many of the practical soil properties important to agriculture, the environment, and engineering purposes, such as ease of cultivation, nutrient and water holding capacities, transmission characteristics, earth dam construction, and susceptibility to erosion. However, with respect to particle size ranges, the subdivision into sand, silt, and clay fractions varies with country and professional institution.^[1] Examples of four of these particle size classifications are shown in Fig. 1.^[2] In defining soil texture, the first three systems shown in Fig. 1 are most widely used in textural class designation.

For describing a soil and/or soil horizon portion of a soil profile, the soil is allocated to a textural class. The textural class descriptors provide an indication of which particle size fraction is dominant, with the exception of a loam where no single size range exerts a dominant influence. In the field, the textural class is estimated by the hand feel of a moist sample of fine earth fraction, when molded between the thumb and forefingers at just below the “sticky point.” In this moisture condition, the soil just begins to stick to the fingers and its moisture content is approximately equivalent to field capacity or the amount of water retained at a water

potential of -33 kPa.^[3] Because the process of hand molding destroys the structure of the soil, the estimate of the textural class will also be related to the particle size distribution. Initially, the soil is remolded several times to form a uniform moist bolus of about the size of a golf ball. Then, the bolus is deformed into threads (see Fig. 2) or ribbons of approximately 3 mm thick (see Fig. 3). The force necessary to deform and shear the bolus and the length of these threads or ribbons increase with clay content. At the same time, if the sample contains a particular size fraction that is readily identifiable by feel to the fingers, this is taken into account in deciding on the soil texture class, e.g., the grittiness of coarse sand or the slippery silky feel of silt. Alternatively, medium and coarse sand can also be seen with a hand lens, and fine sand can be heard by its crunchy grinding sound when remolding and shearing are done close to the ears. Finally, organic matter when present as humus at >10% usually confers cohesion to sandy textures and greasiness to clayey textures^[6] or tends to make sandy and clayey soils feel more loamy in texture as described by Clarke.^[7]

Taking all of the above-mentioned description and criteria into account, soil texturing by hand is essentially a consistency test (see the entry *Consistence*, p. 471) at the sticky point.^[8] It then follows that since the amount of work and cohesion increase in the order of the three principal texture class of sand, loam, and clay, they are often well correlated with the texture classes derived from PSA.^[1,9] Because additional criteria are used in describing the texture of a soil by hand, other than just particle size distribution per se, there are usually more

Fig. 2 A guide to field assessment of texture for mineral soils in the United Kingdom by S. Northcliff, Reading University, and J. R. Landon, Booker Agricultural International.

Source: From Rowell.^[4]

(see the entry *Surface Area: Specific*, p. 2255). Smaller particles possess larger SSA, e.g., SSA for sand is approximately $0.01\text{--}0.1\text{ m}^2\text{ g}^{-1}$, silt approximately $1\text{ m}^2\text{ g}^{-1}$, and clay may range from 10 to $800\text{ m}^2\text{ g}^{-1}$. As most soils contain a considerable amount of clay, it is characterized by large SSA. All physical and chemical processes in the

soil occur at the interface of the soil solids; hence, the larger the SSA, the greater will be the cumulative effect of these processes, and hence the clay fraction plays the major role in this regard. Clays are referred to as the active fraction of the soil, whereas sand and silt are referred to as the skeleton of the soil.

Field texture groups	Ribbon length (mm)	Coherence of the bolus at sticky point	Feel	Other features	Texture grade (synonymous with texture class)	Approx clay %
1 The Sands	Nil	Nil	Sandy	Single sand grains adhere to fingers	1. Sand (S)	Commonly <5
	5	Slight	Sandy	Discolors fingers with an organic stain	2. Loamy Sand (LS)	5–10
	5–15	Slight	Sticky	Sand grains sticks to fingers and discolors with a clay stain	3. Clayey Sand (CS)	5–10
2 The Sandy Loams	15–25	Just coherent	Very sandy	Medium Sand readily visible	4. Sandy Loam (SL)	10–20
	15–25	Just coherent	Very sandy	Fine sand may be heard	5. Fine Sandy Loam (FSL)	10–20
	20–25	Strong	Sandy	Medium Sand easily visible	6. Light Sandy Clay Loam (SCL)	15–20
3 The Loams	About 25	Coherent	Spongy and greasy	No obvious sandiness	7. Loam (L)	25
	About 25	Coherent	Slightly Spongy	Fine sand	8. Loam Fine Sandy (Lfsy)	25
	About 25	Coherent	Smooth	Silky; very smooth when manipulated	9. Silt Loam (SiL)	25 (>25% silt)
	25–40	Strong	sandy	Medium Sand in fine matrix	10. Sandy Clay Loam (SCL)	20–30
4 The Clay Loams	40–50	Strong	Smooth	No obvious sand grains	11. Clay Loam (CL)	30–35
	40–50	Coherent	Smooth	Silky feeling	12. Silty Clay Loam (SiCL)	30–35 (>25% silt)
	40–50	Coherent	Smooth and sandy	Fine sand can be felt and heard	13. Fine Sandy Clay Loam (FSCL)	30–35
5 The Light Clays	50–75	Coherent	Plastic	Fine to medium sand	14. Sandy Clay (SC)	35–40
	50–75	Coherent	Plastic	Smooth and silky	15. Silty Clay (SiC)	35–40 (>25% silt)
	50–75	Coherent	Plastic	Smooth with slight resistance to shearing	16. Light Clay (LC)	35–40
	> 75	Coherent	Plastic	Smooth with a little resistance to shearing	17. Light Medium Clay (LMC)	40–45
6 The Medium & Heavy Clays	> 75	Coherent	Plastic	Fair resistance to shearing	18. Medium Clay (MC)	45–55
	> 75	Coherent	Plastic	Firm resistance to shearing	19. Heavy Clay (HC)	>50

Ease of Cultivation

The ease of cultivation for soils of different textures gives rise to the expressions of “light-textured soils” and “heavy-textured soils” being used for sandy and clayey soils, respectively. Coarse-grained, sandy soils tend to be loose, well aerated, and easy or light to cultivate. Fine-textured soils tend to absorb much water and may become plastic and sticky when wet. Hence, they require much more energy and are heavy to cultivate. Upon drying, they tend to become dense and cohesive.^[14]

Nutrient and Water Holding Capacity and Transmission Properties

The SSA and the magnitude of the electrical charges per unit area of clay and silt determine the cation exchange capacity (CEC) of the soil, which is the number of cations that a unit mass of soil can hold (see the entry *Ion Exchange*, p. 1241). The larger the SSA, the larger is the soil’s nutrient holding capacity, e.g., CEC for kaolinite, illite, and montmorillonite clays range from 3 to 15 mmol kg⁻¹, 10 to 40 mmol kg⁻¹, and 60 to 120 mmol kg⁻¹, respectively. However, fine particle size distribution is generally

Fig. 4 Three of the most frequently used texture triangles. The ISSS is based on particle size of sand (2–0.02 mm), silt (0.02–0.002 mm), and clay (<0.002 mm). The USDA triangle is based on silt fractions of 0.05–0.002 mm and the U.K. triangle on silt fractions of 0.06–0.002 mm.

Source: From Rowell,^[4] McDonald, Isbell, et al.,^[5] Gee & Bauder,^[12] and Soil Survey Staff.^[13]

associated with lower infiltration and drainage rates. Therefore, sandy soils tend to have higher infiltration rates and generally experienced greater leaching, resulting in acid pH and low base saturation. On the other hand, clayey soils tend to have lower infiltration rates and less leaching, resulting in neutral to alkaline pH and high base saturation.

Particle size distribution and SSA are important determinants of the soil's water holding capacity. Water is adsorbed on soil surfaces, and water will accumulate in the pore space between the particles as capillary water, which is held in the soil by the force exerted by the water menisci across the pores between particles. This force is inversely proportional to the size of the pore; hence, water is readily removed or drained from the larger pores. At field capacity, which is the water content of an undisturbed soil at a water potential of –10 kPa, sandy soils tend to have lower water

contents than clayey soils. Similarly, at the wilting point, which is the water content where water is adsorbed onto soil surfaces by a force of –1.5 MPa, sandy soils have lower water contents than clayey soils. However, the plant available water capacity (PAWC), or the amount of water held between field capacity and wilting point, is also lower in sandy soils. The approximate relationship between PAWC and texture is shown in Fig. 5.^[15] Since water at wilting point is adsorbed on the surface of soil particles, it is predominantly affected by the particle size distribution or texture class. However, water at field capacity is adsorbed and is capillary water. The latter is strongly affected by soil structure; this effect increases with surface area and clay content. Where the soil is poorly structured or finely structured, field capacity tends to be highly associated with the predominance of fine pores such as the black earths (curve A in Fig. 5), whereas strongly structured soils have a

Fig. 5 Approximate water holding capacities of different textured soils.

Source: From Foth.^[15]

predominance of large pores and field capacity tends to be lower for the same clay content such as the red Latosols (curve B in Fig. 5). Particle size distribution will affect the pore size distribution of a soil, and consequently, it will influence the soil's transmission characteristic, which is termed as the soil's hydraulic conductivity (see the entry *Hydraulic Conductivity*, p. 1133).

Packing of Particles and Hard Setting Characteristic of Soils

Particle size distribution also affects the potential packing density of the soil or soil aggregates.^[16–18] The presence of sufficient quantities of small particles that will fill the space between the larger particles will result in a massive structureless soil. This generally occurs on soils with 30–35% sand content. One specific soil characteristic associated with the presence of silt and fine sand particles (silty or fine sandy-textured soils) is hard setting, which is a soil characteristic where the aggregates readily break down upon wetting. The structure will not be reformed, and the soil dries out rapidly into a hard consistency. It softens considerably upon rewetting.^[19] Hard setting soils are characterized by low water holding capacities and they alternate rapidly between soft and hard consistencies, often resulting in poor soil physical conditions for most plants.

CONCLUSION

Soil texture is the consistency of a moist soil felt between the fingers and is associated with its particle size distribution. It is affected by clay content and type, silt and organic matter contents of the soil as well as the ion composition on the clay fraction. Texture is a fundamental property that determines the SSA of the soil, which in turn affects many of the physical and chemical properties and behavior of the

soil, such as the soil water and nutrient holding capacities, hydraulic conductivity, and resistance to cultivation.

Tillage Erosion: Description and Process

Michael J. Lindstrom

USDA-ARS-MWA, North Central Soil Conservation Research Laboratory, Morris, Minnesota, U.S.A.

Abstract

Tillage erosion is directly proportional to the degree and scale of topographic complexity. Soil conservation measures that do not include a reduction in tillage erosion will not be effective in controlling soil loss on upper slope landscape positions of cultivated agricultural lands. To reduce soil loss caused by tillage erosion, frequency, tillage intensity (speed and depth), and the size of tillage implements must be reduced.

INTRODUCTION

Tillage erosion is a problem that has been present since the dawn of cultivation. The problem has intensified with increased tillage speed, depth, and size of tillage tools and with the tillage of steeper and more undulating lands. Evidence of tillage erosion is commonly observed as a difference in soil color between hilltops and adjacent lower slope positions. Tillage erosion is defined by the Soil Science Society of America as the downslope displacement of soil through the action of tillage. It is easy to visualize that forward soil movement will be less when tillage operations are conducted in the upslope direction than when conducted in the downslope direction (Fig. 1). This difference in soil translocation distance is a function of gravity. Assuming that the tillage direction often occurs equally in the upslope and downslope directions, then a net downslope displacement of soil will take place. However, it is not an easy matter to move from this simple concept to one that suggests that the soil loss from hilltops in undulating landscapes because of soil translocation by tillage can exceed levels that would be considered sustainable for crop production.

Tillage erosion has often been described in qualitative rather than quantitative terms. Evidence of the mass downslope movement of soil by tillage has been present for years. One example frequently cited comes from the Palouse region of the Pacific Northwest of the United States^[1] where soil banks, 3–4 m high, have developed at fenceline locations on steep side slope. These soil banks are the result of moldboard plowing, where the tillage above the fenceline turned the furrow slice toward the fenceline, and tillage below the fenceline turned the furrow slice away from the fenceline. In studies designed to measure the effect of soil variability across landscapes on crop production potentials, tillage has been implicated as the cause for observed downslope soil movement and an increased variability of soil properties.^[2,3]

Examination of stereoscopic aerial photographs taken in 1947 and 1991 in the Loam Belt of Belgium showed a severe surface lowering on the top of the hillslopes and on hillslope convexities. Deposition occurred on the lowermost parts of the hillslope in hillslope concavities and in topographic-defined convergence lines. The observed pattern differed markedly from that expected from water erosion processes, indicating that soil redistribution was dominated by tillage operations.^[4]

DETERMINATION OF TILLAGE EROSION

A simple linear regression of the form $Y = a + b(S)$ has been developed,^[5,6] which describes the relationship between slope gradient (S) and mean soil translocation distance (Y) in the direction of tillage. Slope gradients were considered positive when tilling upslope and negative when tilling downslope. Expanding on this relationship, it has been proposed^[6] that tillage translocation could be considered a diffusion-type geomorphological process, similar to rain splash and soil creep, and characterized by a single constant, the tillage transport coefficient (k).

$$k = -D\rho_b B \quad (1)$$

where D is the depth of tillage (m), ρ_b is the soil bulk density (kg/m^3), and B is the slope of the linear regression equation of the relationship between soil displacement (m) and slope gradient (m/m). Using this relationship, the unit soil transport rate in the direction of tillage (Q_s) at any specific point in a field can be calculated as:

$$Q_s = kS \quad (2)$$

where S is the slope gradient (m/m). Representative tillage transport coefficients (k values) for moldboard plow tillage have ranged between 230 kg/m and 330 kg/m .^[6] Agricultural fields commonly undergo a series of tillage operation resulting in k values of 400–600 kg/m .

Fig. 1 Relative soil displacement distances when the thrust is upslope vs. downslope.

It is not possible to directly calculate soil erosion using Q_s , because this value essentially represents a soil flux rate at a cross section for a specific tillage operation or series of operations. However, soil loss or gain will result when, for an elementary slope segment of unit width, the incoming flux is different from the outgoing flux:

$$E = (Q_{s, \text{in}} - Q_{s, \text{out}})/X \quad (3)$$

where E is the tillage erosion rate (kg/m^2) and X is the length (m) of the elementary slope segment under consideration. Because Q_s is directly proportional to the slope gradient, soil loss or gain will be proportional to the change in slope gradient. Soil translocation by tillage will result in soil loss in convex slope positions such as crests and shoulder slopes because there is an increase in slope gradient and thus an increase in soil transport rate. Conversely, soil deposition will take place in concave slope positions in the foot- and toe-slope positions. When slope gradients between adjacent elemental slope segments are equal, irrespective of their magnitude, no net soil loss or gain takes place because the $Q_{s, \text{in}}$ equals $Q_{s, \text{out}}$. Thus, in backslope positions where slope gradients are commonly the greatest, exhibiting the greatest soil transport rate, net soil loss or gain will be minimal provided slope gradients remain constant. Therefore, the rate of soil gain or loss will depend on the unit transport rate and the degree of change in slope gradients:

$$E = \Delta Q_s / X \quad (4)$$

The magnitude of soil erosion rates by tillage vs. water is affected by many variables, i.e., topography, rainfall intensity, tillage intensity (depth and frequency), and land use. Examination of the relationship between a range of topographic parameters and ^{137}Cs -derived erosion rates, from fields in the United Kingdom,^[7] showed that the highest correlation was between erosion rate and landscape curvature at four of the five sites investigated. These results were not consistent with the dominance of water erosion, where slope angle and upslope lengths, or areas, are the primary influences. In a study comparing the roles of tillage and water erosion in landform development on agricultural land in Belgium,^[8] it was suggested that if water erosion were the dominant process, the landscape would be characterized by increased incision of the

concavities and convergent waterways. A gradual increase in slope angles on upland convex slopes was also noted. In contrast, tillage produces maximum erosion on convex slopes, leading to reduced slope angles and infilling of concavities and hollows. The pattern of landform development observed was an infilling of the slope concavities and convergent waterways by sediment displaced through tillage that then more compensated for the lower frequency, but more visible, rill and gully incision. The pattern indicates that, despite high susceptibility of the area to water erosion, landform development in this agricultural landscape is dominated by tillage erosion processes. These processes result in a reversal of the expected landscape evolution, with a gradual obliteration of topographic features. Other studies have indicated that tillage erosion rates are of the same order of magnitude as water erosion.^[9,10]

EFFECTS OF TILLAGE EROSION

The tillage transport coefficient (k value) is a measure of the mean distance a mass of soil per unit width is moved by tillage, in a specified direction relative to the direction of tillage. The soil mass is translocated in the forward direction (parallel to the direction of tillage) but is also translocated in the lateral direction (perpendicular to the direction of tillage). Determination of k values has mostly been in the forward direction. However, using the mean displacement distances does not fully describe soil translocation. To illustrate, a single pass with a chisel plow may move 70 kg of soil forward per meter width of tillage. The mean forward displacement of this 70 kg of soil may be 40 cm, but significant quantities of soil may be moved as little as 5 cm or as much as 300 cm. Soil displacement will vary across the width of a tillage implement because of the spacing and arrangement of the individual tillage tools. This variation in distance over which soil is translocated is important because it affects the distance that soil constituents (amendments and contaminants) are dispersed or mixed by tillage.

The rate of soil loss by tillage erosion within topographically complex landscapes is several times more than is considered sustainable for crop production. Soil loss in a convex slope position in the Ontario Province of Canada was estimated to be 54 t/ha/yr.^[11] Estimates made using resident ^{137}Cs indicate that between 70% and 100% of soil lost in convex slope positions is the direct result of tillage erosion.^[12] Crop yield reductions of 40–50% have been associated with these eroded landscape positions throughout southwestern Ontario.^[13]

Although tillage erosion can result in considerable soil loss and accumulation within fields, soil is not directly lost from fields by tillage erosion. However, tillage erosion exposes subsoil material on upper slope positions, which may become more susceptible to wind and water erosion. Furthermore, the redistribution of soil by tillage erosion

delivers topsoil to areas of concentrated overland water flow on both the microtopographic scale (i.e., rills) and the macrotopographic scale (i.e., convergent landforms).^[11,14] As such, tillage erosion acts as a delivery mechanism of soil, which is then subject to water erosion.

Soil translocation by tillage produces maximum erosion at abrupt convex slope positions, causing a reduction in slope angles, and an infilling of hollows, resulting, over time, in a gradual obliteration of topographic features. As tillage erosion proceeds, the erosion process occurs over an increasingly larger area. In contrast, when water erosion is the dominant process, the landscape is characterized by increased incision of concavities and ephemeral gullies. A gradual increase in slope angle on convex slope positions also occurs.

CONCLUSION

Tillage erosion is directly proportional to the degree and scale of topographic complexity. Soil conservation measures that do not include a reduction in tillage erosion will not be effective in controlling soil loss on upper slope landscape positions of cultivated agricultural lands. To reduce soil loss caused by tillage erosion, frequency, tillage intensity (speed and depth), and the size of tillage implements must be reduced.

Tillage Erosion: Measurement Techniques

David A. Lobb

Department of Soil Science, University of Manitoba, Winnipeg, Manitoba, Canada

Abstract

Tillage erosion is the redistribution of soil that occurs within a landscape as a direct result of tillage. Variations in the amount of soil moved by tillage cause loss and accumulation. Tillage translocation is the movement of soil by tillage; variability in translocation is affected by the design and operation of tillage implements and by the topographic and soil properties of landscapes. A wide variety of materials and methods have been used to measure tillage erosion. There are two general methods of measuring tillage erosion: measurement of soil loss and accumulation at points over the surface of a landscape and measurement of tillage translocation at points over a landscape and the difference between those points.

INTRODUCTION

Tillage erosion is the redistribution of soil that occurs within a landscape as a direct result of tillage. Variations in the amount of soil moved by tillage cause loss and accumulation. Tillage translocation is the movement of soil by tillage; variability in translocation is affected by the design and operation of tillage implements (implement width and length, tool shapes and arrangement, tillage depth and speed, available power to maintain operating speed and depth under changing conditions) and by the topographic and soil properties of landscapes (slope gradient and curvature and soil texture, bulk density, and moisture content). Typically, tillage results in the progressive downslope movement of soil, causing severe soil loss on upper slope positions and accumulation in lower slope positions (Fig. 1). A wide variety of materials and methods have been used to measure tillage erosion.

The earliest scientific study of tillage erosion took place in the United States in the 1930s.^[1] Since then, 40–50 studies have been conducted around the world, most undertaken between 1995 and 2005.^[2] Very few of these studies used identical materials and methods, reflecting the evolution of experimental techniques and the diversity of experimental conditions. There are two general methods of measuring tillage erosion: measurement of soil loss and accumulation at points over the surface of a landscape and measurement of tillage translocation at points over a landscape and the difference between those points.

TRANSLOCATION MEASUREMENTS

Tillage translocation is normally measured with a tracer that is incorporated into the soil in plots. The distributions of the tracer before and after tillage are used to calculate translocation—forward translocation from the distribution

parallel to the direction of tillage and lateral translocation from the distribution perpendicular to the direction of tillage (Fig. 2).

There are two methods of calculating translocation from tracer distributions. For the more common method, the quantity of soil translocated per unit width of tillage is calculated directly from the tracer distributions.^[3] For the less common method, a summation curve is generated from a tracer distribution by employing convolution, and translocation per unit width of tillage is calculated from this curve.^[4,5] Both methods provide accurate measures of translocation but the latter provides additional information regarding the distance over which translocated soil is dispersed.^[6] Translocation can be expressed as a length (averaged over the depth of tillage), a volume, or a mass.

Tillage erosion is expressed similarly to wind and water erosion, i.e., a change in soil mass per unit area or a change in elevation. The calculation of tillage erosion from translocation measurements is simply the difference in translocation between two points, divided by the separating distance—An increase or decrease of kilograms of soil translocated per meter width of tillage divided by the meters of distance between measurements.

Within a complex soil landscape, numerous measurements of tillage translocation may be required. Plots should be placed so that the variability in translocation is characterized in detail. Where slope gradient has been assumed to be the dominant factor affecting soil movement, plots should be located over the full range of gradients. Greater attention should be paid to those areas where slope gradient is changing (i.e., convex and concave areas), because changes in slope gradient result in soil loss and accumulation. A pair of plots positioned at the steepest point along a slope profile—one tilled upslope and the other tilled downslope—provides measures of the minimum and maximum translocation, net downslope translocation, and the total soil loss from the upper slope and the total soil

Fig. 1 Variability of translocation in hilly landscape (upslope–downslope tillage): Soil loss occurs on convex areas and accumulation occurs on concave areas. (Translocation is indicated by arrows, its magnitude by their lengths.)

accumulation on the lower slope. Although the minimum and maximum values of translocation occur at this point on the hillslope, if the gradient in this region of the slope is uniform, no soil loss or accumulation will occur at this point.

Tracers consist of plot tracers and point tracers. Point tracers are individually labeled tracers of various shapes and materials, such as steel nuts^[7] or plastic spheres.^[8] Plot tracers are used to label a volume of soil; they can be physical (e.g., gravel^[9]) or chemical (e.g., ^{134}Cs ^[3] and chlorine^[4]). Point tracers also represent a volume of soil but they have the distinct advantage that they can be used to characterize the complexity of soil movement in 3-D. However, plot tracers provide a more accurate measure of bulk soil movement in 2-D.

After tillage, soil is sampled and analyzed to determine the distribution of the tracer. Sampling usually involves destruction of the site, eliminating the possibility of successive translocation measurements from recurrent tillage operations. Nondestructive sampling methods do exist.^[4] Sampling must be carried out as soon as possible after tillage to isolate the movement of soil by tillage from that by other processes. Other measures can also be taken to isolate soil movement by tillage.^[5]

The precise relocation of plots and the recovery of the tracer are important considerations when sampling. Precise plot relocation is best achieved by plot making materials where the base of the plot is left in place throughout the measurement process.^[10] This plot base is used as a reference for tracer placement and movement. An acceptable level of tracer recovery is greater than 95%. Tracer that is not recovered is usually the result of not sampling deep enough or to the full extent of forward and lateral movement.

Fig. 2 Simplified illustration of soil translocation by tillage: T^f = forward translocation; T^l = lateral translocation; and W_T = unit width of tillage.

Every effort should be made to sample the full extent of tracer movement because small quantities of unrecovered tracer at the furthest extent can greatly impact the accuracy of erosion measurements.

The design of plots is possibly the most important consideration when using tracers. Even under controlled operating conditions, the movement of soil during tillage is inherently variable because of the nature of soil–tillage interactions. Soil strains and fails during tillage, and tools and implements flex and shift—The “flow” of soil during tillage is not steady. For accurate measurement of soil movement by tillage, plots must be sufficiently long and wide to filter out this “noise.” The length of plots used in tillage erosion studies has ranged from a few centimeters to a few meters. As stated previously, a longer plot provides a better measure of the average movement of soil by tillage. The movement of soil varies across the width of tillage as a function of the tool type, arrangement, and spacing. For accurate measurement of soil movement by tillage, the width of the plot must be a multiple of the unit width of tillage. For a single pass of a simple tillage implement, the unit width is the distance between two adjacent tools. However, for an implement with multiple tool types or for a sequence of different implements, establishing the unit width of tillage may not be possible. To reduce measurement errors associated with plot width, the plot must be as wide as possible. The paths of a tillage implement overlap in the field (as much as 10%), with the exception of implements such as the moldboard plow, causing additional soil movement at the edges of each path. To account for this additional movement, plot widths must be equal to the spacing of implement paths; however, this is not practical in most cases. The depth of plots must exceed the maximum depth of the tillage operation(s) under examination. Tillage depth can vary greatly within a landscape, so caution must be used in estimating the maximum tillage depth—it is better to overestimate tillage depth than to underestimate.

Tillage translocation can also be measured using detailed elevation surveys of the soil surface. The redistribution of soil volume, along with soil bulk density, can be used to measure soil translocation.^[1,9] There are two good examples of this technique. In the study of tillage erosion by contour moldboard plowing, the profiles of furrow slices turned upslope are compared to those of furrow slices turned downslope—The difference is a measure of net downslope translocation. In the study of tillage erosion by hoeing on steep slopes (soil is only hoed downslope), the profiles of the furrow created at the top of the slope and the ridge created at the bottom are measures of downslope translocation.

MEASUREMENTS OF LOSS AND ACCUMULATION

Soil loss and accumulation by tillage erosion can be estimated from changes in soil properties or surface elevation. In most

cases, the loss or accumulation from a single tillage event or an annual sequence of events would be too small to measure accurately; consequently, measurements are usually made over a period of many years. The distribution of these changes over the surface of the landscape allows the assessment of soil redistribution.

Soil surface elevation is commonly used as an indicator of recurrent tillage erosion. The elevation within a tilled portion of the landscape is compared to an adjacent non-eroding landscape feature, such as a fenceline or hedgerow. Decreases in surface elevation on upper slope landscape positions and increases in elevation on lower slope positions are classic evidences of tillage erosion. Using tillage history and elevation changes, it is possible to estimate the average annual rate of tillage erosion.

Soil properties, such as the amount of organic matter and carbonates, are commonly used as indicators of recurrent tillage erosion. Organic-poor, carbonate-rich subsoil exposed on the surface of upper slope landscape positions is a classic evidence of soil loss by tillage erosion. Accumulation of organic-rich soil in convergent slope positions is also a classic evidence of tillage erosion. However, such familiar soil properties are not considered reliable estimators of soil erosion. Radioisotopes found in soil are used to accurately estimate soil erosion; the most frequently used are ^{137}Cs and ^{210}Pb .^[5,11] ^{210}Pb naturally occurs and ^{137}Cs originates from human use of nuclear radiation. Both isotopes contact the soil through atmospheric deposition and remain concentrated in the surface soil. The spatial distribution of radioactivity is compared to a baseline distribution or to a single value based on a non-eroded reference site. This technique is suited to timescales of 5–40 yr for ^{137}Cs and 50–150 yr for ^{210}Pb . Soil magnetic susceptibility^[12] and fly ash concentrations have been used to estimate soil erosion.

The use of long-term soil loss and accumulation to estimate rates of tillage erosion is problematic in that it is not possible to isolate individual erosion processes. Furthermore, erosion processes interact. The contribution of tillage erosion to the total soil redistribution within a landscape must be determined based on the signature patterns of redistribution by individual erosion processes.^[13]

CONCLUSION

The assessment of soil erosion in cultivated landscapes requires the measurement of tillage erosion. Tillage erosion is measured directly by measuring the movement of soil by tillage – tillage translocation. Translocation is measured using plot tracers or point tracers. Careful consideration

must be given to several aspects of the techniques used to measure tillage translocation and tillage erosion to ensure accurate and meaningful information. Techniques for measuring tillage translocation and tillage erosion are well developed but are undergoing enhancements.

Tillage Erosion: Properties and Productivity Effects

Tom E. Schumacher

*Department of Plant Science, South Dakota State University, Brookings,
South Dakota, U.S.A.*

Abstract

The relation between soil productivity and soil erosion is complex. Soil productivity is dependent on the ability of the soil to provide water, nutrients, and oxygen to the plant root system as well as to limit the exposure of the root system to toxic gases or solutions. Tillage erosion, the downslope displacement of soil through the action of tillage operations, is a specific form of soil erosion. The impact of tillage erosion on soil productivity is primarily related to soil removal from a specific landscape position and deposition in another part of the landscape. As a result, many of the causes of change in soil productivity attributed to other forms of erosion also apply to tillage erosion. Tillage erosion acts on soil productivity through the loss of effective rooting depth, loss of plant nutrients, and loss of plant-available water.

INTRODUCTION

The relation between soil productivity and soil erosion is complex. Soil erosion is defined as the wearing away of the land surface by natural or anthropogenic agents that abrade, detach, and remove soil from one point on the earth's surface and deposit it elsewhere.^[1] The capacity of a soil to produce a certain yield of crops or other plants within a specified system of management is defined as soil productivity.^[1] Soil productivity is dependent on the ability of the soil to provide water, nutrients, and oxygen to the plant root system as well as to limit the exposure of the root system to toxic gases or solutions. The processes involved in the supply of beneficial and toxic compounds are dependent on storage capacities and transport rates that are determined by an array of soil properties. Soil and topographic properties that control the inherent productivity of a specific field location include slope, effective root zone depth, bulk density, available water-holding capacity, plant-available nutrient content, soil aeration, water infiltration and percolation, soil pH, aluminum and manganese concentration, root zone cation exchange capacity, aggregate stability, salinity, and nutrient cycling by soil biological organisms.^[2–4] As soil erodes, soil properties of the root zone often are altered. Consequently, storage capacity and transport rates of compounds critical for plant growth also change. Several reviews have been written on various aspects of the subject of soil erosion, soil properties, and productivity.^[5–7]

Tillage erosion, the downslope displacement of soil through the action of tillage operations,^[1] is a specific form of soil erosion. The impact of tillage erosion on soil productivity is primarily related to soil removal from a specific landscape position and deposition in another part of the landscape. As a result, many of the causes of change in soil

productivity attributed to other forms of erosion also apply to tillage erosion. Lal^[8] lists several direct effects of soil erosion on crop yield. These include a reduction in effective rooting depth, loss of plant nutrients, loss of plant-available water, loss of land area (due to gully formation and unfavorable conditions in depositional areas), and damage to seedlings from the action of the erosion agent. Of these, tillage erosion acts on soil productivity through the first three, namely: loss of effective rooting depth, loss of plant nutrients, and loss of plant-available water.

TILLAGE EROSION AND SOIL PROPERTIES

Soil productivity changes due to tillage erosion at eroding landscape positions are dependent on the properties of the underlying soil horizons and the severity of soil loss. Lal^[8] describes three scenarios of erosion-induced change in soil productivity that depend on subsoil properties. Some soils may have no change in soil properties affecting crop growth. These soils usually are deep soils with relatively uniform soil properties in and below the root zone. A second scenario involves rare cases where soil properties in subsurface soil horizons are more favorable for plant growth than in the A horizon. In these soils, soil productivity actually increases with erosion. A third scenario, which is by far the most common in agricultural fields, involves soils that drop in productivity as soil is removed from the surface. These soils have subsurface horizons with soil properties that are less beneficial to plant growth than soil in the A horizon.

Tillage erosion changes soil properties and thus soil productivity by at least two mechanisms. One mechanism involves the net loss of topsoil from field locations where the slope forms a convex shape such as the shoulder

landscape position. A second mechanism involves the mixing of topsoil with subsoil exposed by tillage erosion as soil is translocated by the tillage operation beyond the eroding landscape position.

Over a period of time, tillage erosion can result in the exposure of subsoil. Tillage operations spread and mix subsoil with topsoil as soil is translocated downslope even though there may be no net loss of soil in the translocation zone.^[9,10]

This mixing of topsoil with subsoil spread by tillage equipment can result in a change in soil properties that reduces soil productivity in adjacent non-eroding landscape positions. The subsoil materials over time will become mixed from the zone of soil loss (convex slopes) to the zone of deposition (concave slopes).^[11]

LANDSCAPE POSITION AND SOIL PRODUCTIVITY

The effects of different erosion agents on soil productivity can often be better differentiated by their location of

action within the landscape than by unique changes in soil properties. Tillage erosion occurs in topographic positions that are convex such as shoulder positions.^[12] Water erosion primarily occurs in mid-to-lower portions of a backslope.^[13] Wind erosion occurs primarily on coarse-textured soils and is most severe on shoulder positions facing into the prevailing wind.^[14] Tillage erosion appears to be responsible for most of the soil erosion occurring in shoulder positions where wind erosion is not a predominate agent of erosion.^[15] Therefore, soil productivity losses observed in shoulder positions and on knolls in humid and semihumid regions are likely the result of tillage erosion.

The shoulder position prior to agriculture often has lower solum thickness.^[16] As a result, changes in soil productivity from tillage erosion may occur more rapidly and with greater intensity per unit of soil erosion because the soil tends to be naturally shallower in the shoulder position. Fig. 1 illustrates a 32-ha field from Central South Dakota showing variation in winter wheat (*Triticum aestivum* L.) yield, predicted soil gain/loss from moldboard plow tillage, and available phosphorous based on the Olsen P test.^[17]

Fig. 1 Predicted soil loss from tillage erosion, winter wheat yield, and Olsen P test from a 32-ha field in Central South Dakota. Soil gain (deposition) is represented by positive values in the middle graph, while soil loss (erosion) is represented by negative values.

Lower yields in this field tended to be associated with field areas that had high rates of tillage erosion, lower plant-available phosphorous, and exposed subsoil material.

MODELING TILLAGE EROSION AND SOIL PRODUCTIVITY

The complexity of the soil erosion–productivity relationship is such that few generalizations can be made. The mechanisms by which tillage erosion impacts soil productivity will change depending on soil and climate. Site-specific soil property measurements can be very expensive and time-consuming if applied to large-scale fields. Modeling erosion events, erosion-induced changes in soil properties within the root zone, and soil property–productivity relationships is one approach that may be used to evaluate fields. In one study, a tillage erosion model^[18] and water erosion model^[19] were used to evaluate the effects of erosion on soil property distribution in a closed depressional landscape.^[20] The erosion-induced change in soil properties was then coupled with a productivity index,^[21] a model that relates soil properties to soil productivity. Model results showed that considerable variability in soil productivity was introduced into the landscape by the combined action of tillage and water erosion.

In most cases, soil erosion is because of an interaction of various erosive agents such as tillage and water, tillage and wind, or a combination of all the three agents. An evaluation of soil productivity within eroded/eroding landscapes must take into account the interaction of all erosive agents on soil properties and the specific effect of soil properties as related to the supply of water, oxygen, and nutrients to the root systems of growing plants. Using less intensive tillage operations has the beneficial effect of reducing soil loss from all the three erosion agents, thus reducing the rate of change in soil productivity. However, a reduction in tillage operations by itself is less likely to reverse changes in soil properties and productivity caused by erosion. The restoration of productivity to eroded soils is often difficult, time-consuming, and likely to require the integrated application of older and yet-to-be developed technology.

Tillage Erosion: Relationship to Water Erosion

Gerard Govers

Laboratory for Experimental Geomorphology, Catholic University of Leuven, Leuven, Belgium

Abstract

Tillage and water erosion interact in various ways. It has long been known that tillage affects the soil's resistance to detachment and transport by water. Soil tillage alters the soil structure, reduces soil's bulk density, breaks up the soil crust, and incorporates superficial residue into the soil. However, these phenomena are not directly related to the fact that during tillage operations, soil displacement and tillage erosion occur. Tillage translocation and erosion have specific effects on the water erosion processes. Conversely, water erosion processes may affect tillage translocation and erosion. We discuss the interactions between tillage erosion and water erosion that occur at various timescales.

TILLAGE EROSION AND WATER EROSION

On a short timescale, tillage erosion acts as a delivery mechanism for water erosion. Water erosion is often the strongest along the central axis of hill slope concavities (hollows); here, a large amount of surface runoff is concentrated, whereas slope gradients are often relatively high.^[1] This often leads to ephemeral gully erosion.^[2] At the same time, important amounts of soil are deposited here as a result of tillage. The delivery of sediment by tillage may exceed the average water erosion rate, in which case net deposition will occur.

Conversely, if soil delivery by tillage is lower than the average water erosion rate, the result will be net incision. The balance depends upon the relative intensity of both processes and the landscape morphology. Deposition by tillage will increase with increasing slope concavity. On the other hand, water erosion rates will increase with increasing slope gradient and upslope water contributing area. The interaction between tillage and water erosion is not one way; when ephemeral gullies form, farmers will often undertake special tillage operations to fill them in, which then leads to an increased soil displacement by tillage.

On a longer timescale, tillage translocation and erosion affect topography. Tillage translocation leads to the deposition of soil in concavities (hollows) as well as on the upslope side of field borders. It causes soil erosion on convexities (shoulders) as well as the downslope side of field borders. Therefore, the process will lead to a diminution of the overall relief energy within a field and the water erosion risk, as the latter strongly depends on the slope gradient.

The accumulation and erosion of soil at field borders can be fairly rapid, leading to the development of soil

banks of several meters high over a time period of a few decades if the soil is consistently thrown downslope during tillage. In intensive tillage systems in Western Europe, concavities are filling at a rate of 5–20 mm yr⁻¹ because of tillage deposition, while convexities are typically eroding at rates of 0.5–2 mmyr⁻¹.^[3] Considering a typical slope of 100 m having an average gradient of 10%, it will take 44–180 years to reduce average slope gradient by 1% point, neglecting the effects of water erosion on topography. Changes in relief energy will be more rapid when convexities and concavities are more pronounced, as is the case on many moraine landscapes in Northern Europe and America.^[4]

In many agricultural systems, slopes are interrupted by vegetative borders and/or water diversion structures to reduce the water erosion risk. In such systems, soil translocation by tillage will lead to much more rapid and important changes in topography. For example, tillage translocation will gradually decrease the slope of the field strips because of the deposition of soil at the downslope end of the field and erosion at the upslope end (Fig. 1).^[5] Again, the speed at which these changes occur depends on the initial topography and the intensity of the tillage erosion process. Changes will be more rapid when initial slopes are high, tillage is intense, and field borders are closely spaced. Calculations for 6-m wide, slow-forming terraces in Ecuador show that tillage erosion will reduce the initial slope gradient of 30% to approximately 6% in 25 years using traditional tillage techniques. In some cases, this effect may be deliberately speeded up by consistently throwing the soil downslope when tilling the field strips.

Some positive effects of the reduction of within-field slope gradient may be counteracted by erosion processes specifically related to the soil banks. In some cases,

Fig. 1 Schematic representation of the evolution of the slope profile by tillage erosion with (B) and without (A) the presence of diversion structures or terraces.

gully erosion may form on the terrace banks. Such bank gullies can be initiated by piping caused by animal activity, cracking, and/or mass transport processes occurring on the banks. The risk of bank failure and the speed at which bank gullies will develop depend, to a large extent, on the properties of the soil profile.

Evidently, water erosion may also lead to topographical changes affecting tillage erosion rates and patterns. Generally, water erosion will tend to incise the landscape, leading to steeper slope gradients and more pronounced convexities and concavities. This can be seen in its most extreme form in badlands. As a consequence, the potential for tillage erosion is increased. However, the reverse may also occur when the within-field deposition of sediment by water is important. This deposition will lead to a reduction in relief energy and, eventually, a reduction in tillage erosion.

Tillage erosion also affects water erosion by changing soil properties. The extent and nature of such changes depend on the initial properties of the soil. Generally, such changes will be more important when the soil's A horizon is shallow and when there is a large difference in properties between the A horizon and the lower soil horizons.

In the first phase, tillage erosion leads to the exposure of subsoil on convexities and at upslope field borders. If tillage erosion continues for a sufficiently long period, this subsoil material will be transported further downslope. During downslope transport, the subsoil material is mixed with the original topsoil. After a long time period, the properties of the plough layer will be predominantly determined by the properties of the original subsoil at convexities and upslope field borders. They will gradually change to those of the original topsoil in the downslope direction. The area where subsoil properties dominate will increase with time.

In the final stage, a soil profile inversion may occur over large parts of the landscape, whereby the original topsoil material is buried by a layer of subsoil material eroded further upslope. The effect of these changes on water erosion rates and patterns may vary. On stony soils, tillage may increase stone cover on convexities, thereby

leading to a considerable decrease in water erosion risk from the protective effect of the stones.^[6] However, in most cases, the properties of the subsoil are such that tillage erosion will lead to an increase in the water erosion risk. Very often, the subsoil material has a lower structural stability than the original topsoil, which causes a higher sensitivity for crusting and more runoff generation in the areas of exposure.

Because the subsoil material is exposed in upslope landscape positions, this will increase the erosion risk over the whole landscape. The runoff generated in the upslope landscape positions increases soil erosion further downslope. This process may be further enhanced by reduced vegetative growth on the less-productive tillage eroded areas, and poorer soil cover and increased erosion rates. In concave landscape positions, the potential negative effect of water erosion on soil quality is to some extent compensated for by tillage deposition. Tillage deposition causes the depth of the A horizon to either decrease more slowly or increase in these landscape positions, thereby potentially promoting carbon sequestration.^[7] However, in the long term, the original A horizon may become buried by subsoil material.

Changes in soil properties like soil texture and organic matter content caused by water erosion are unlikely to affect tillage erosion to a great extent. Results of tillage erosion experiments suggest that tillage speed and depth, tillage tool geometry, and dynamic soil properties, like bulk density and moisture content, have a far greater influence on tillage displacement and erosion.^[8]

Finally, different spatial signatures of tillage and water erosion have implications for the calculation of average soil erosion rates at the field scale and for the assessment of effects on soil quality. Tillage erosion causes only soil redistribution within a field, so that the average soil erosion rate over the field is zero. The intensity of tillage erosion may be better assessed by calculating an average rate over the eroding part of the landscape, as is often done for water erosion. To calculate an overall soil erosion rate, erosion and deposition rates for tillage and water erosion must be calculated using a spatially distributed model, so that soil losses and gains can be assessed at each landscape position. These may be combined to produce a map of the total soil erosion or deposition rate at each point.^[9] This rate can then be calculated by taking the average of the values for the eroding landscape positions.

Because of the compensating nature of water and tillage erosion, the total average soil erosion rate that is calculated using this procedure will generally be much lower, but it will also be more realistic than the sum of the separately calculated average water erosion rate and the average tillage erosion rates. Similarly, the assessment of the soil quality effects of erosion and deposition by tillage and water is only possible using a spatially distributed model that accounts for both processes. Both water erosion and tillage erosion contribute to the redistribution of soil

carbon, albeit in a significantly different way: The effect of erosion on the overall carbon budget of arable land can only be understood if both processes are correctly accounted for.^[7]

CONCLUSION

Water and tillage erosion interact in various ways. On the long term, the processes mainly interact through their differential effect on topography. While tillage erosion essentially tends to reduce the water erosion risk by smoothing the topography, water erosion acts inversely. On a shorter timescale, the effect of tillage erosion on the spatial variation of soil properties at the field scale has a significant effect on the intensity and spatial variability of water erosion. The interaction between water and tillage erosion not only needs to be considered when calculating the overall erosion risk but is also important for a correct understanding of the effect of water and tillage erosion on the carbon budget of arable land.

National Sedimentation Laboratory, Arkansas State University, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Jonesboro, Arkansas, U.S.A.

Abstract

All tillage moves soil laterally as well as vertically. With each tillage operation, soil preferentially moves downslope, and some soil usually leaves the tilled zone in the form of clods deposited along field borders. Over time, these clods, along with stones removed from the tilled area and sediment deposited by runoff, coalesce to form terraces or lynchets. The formation of such terraces may or may not be desirable but can hardly be avoided if field boundaries are fixed for long periods of time. This entry reviews research into terrace formation by tillage, identifies ways in which these terraces can be advantageous to soil and water conservation, and discusses problems that have been recognized with tillage terraces.

INTRODUCTION

All tillage moves soil laterally as well as vertically. While a few implements such as a moldboard plow or a one-way disk plow throw soil to only one side, most tillage implements—including tandem disks, chisel plows, harrows, and cultivators—throw soil to both sides. With such implements, a tillage operation along the contour moves some soil uphill, more soil downhill, and still more soil along the contour in the direction of travel.^[1–3] Within an undulating field, each tillage operation flattens the topography, as soil is progressively removed from convexities and is deposited in depressions and other concavities.

Field boundaries interrupt soil fluxes caused by tillage and can result in the formation of two distinct classes of terraces. On sloping land with untilled strips, tillage moves soil toward a down-gradient untilled strip and away from an up-gradient untilled strip. This leads to aggradation of soil upslope of untilled strips and degradation of soil downslope of them and causes the gradual formation of bench terraces. The speed of bench terrace formation is greater where the spacing between the untilled strips is narrower, where the initial slope is steeper, and where tillage is more intense. The other class of terraces formed at field boundaries is due to local ridges and furrows. Depending on tillage tool design and operation, some soil often leaves the tilled zone in the form of clods deposited along field borders. The combination of clods thrown from the tilled area and dead furrows left behind creates small terrace channels at the margins of tilled areas that can intercept and alter runoff flow patterns. The impact of these small gradient terraces on hydrology is greatest on gently sloping lands. This entry

reviews research into terrace formation by tillage, identifies ways in which these terraces can be advantageous to soil and water conservation, and discusses problems that have been recognized with tillage terraces.

ANCIENT LYNCHETS

Archeologists use the term “lynchets” to refer to soil banks that are believed to be remnants of ancient agricultural activities. These ancient soil banks have been studied intensively for over 100 years. Lynchets dating from the bronze age, iron age, and medieval periods are all generally recognized to be the morphological response on a hillslope to the presence of field boundaries in cultivated landscapes.^[4] While medieval lynchets tend to be oriented along the slope, older “Celtic fields” were often square and bounded by lynchets on all sides,^[5] and some lynchets are oriented up and down the slope.^[6] Lynchets form at all field boundaries either bounded by untilled grass strips (balks), hedge rows, paths, fences, or ditches.^[6,7] Frequently, lynchets contain piles of stones at their core. These stones may have marked property boundaries or may simply represent convenient disposal locations as stones were removed from fields.

CONTEMPORARY LYNCHETS

Contemporary lynchet formation has been observed and described around the globe.^[7–23] The presence of a physical boundary such as field borders, fences, hedge rows, or vegetative barriers creates a local interruption of the soil

movement created by tillage, resulting in morphological changes in the vicinity of the boundary. Erosion or deposition occurs depending on the orientation of terrain slopes with respect to the boundary. When the tilled terrain slopes away from the boundary, the net soil translocation in the downhill direction creates erosion near the boundary, while soil deposition occurs where the terrain slopes toward the boundary. Localized erosion also occurs wherever tillage implements first engage the soil, and deposition occurs at locations where tillage tools are removed from the ground and turned around. The aggrading side of a field boundary is often termed a “positive lynchets,” while the degrading side (the upslope edge of a tilled area) is termed a “negative lynchets” (Fig. 1). Positive lynchets have deeper, more fertile, and more productive soils than those on negative lynchets, where subsoil may be exposed.^[12,19,21,22,24]

A modern example of lynchets formation is provided by a field subdivided by grass hedges planted on the contour in North Mississippi, U.S.A., which was surveyed periodically over 16 years (Fig. 1). Tillage between the hedges led to erosion in the downslope side of each hedge, as soil was displaced in the downhill direction by tillage, and the hedges caused deposition of sediment transported by water and tillage on their upslope side. Lynchets developed rapidly once contour tillage with disks and chisel plows began between the grass hedges.^[25,26] Changes in elevation reflected the combined influences of tillage and water erosion. At each grass hedge, lynchets of up to 0.8 m formed during a period of 16 years, and the average slope of field was reduced from 7.2%, when the hedges were first established, to 3.7%.^[27]

Hand tillage with a hoe differs from that associated with draft animals or tractors because soil usually moves

in a direction opposite of the workers’ travel. Because hoeing is hard work, it is common for soil to move mainly downhill, with work starting at the bottom of a field and proceeding upslope.^[19] Again, the net result is gradual terrace formation.

Soil erosion by water generally increases with increasing slope length because of an accumulation of runoff. This should lead to the development of concave hillslope profiles with little change in elevation near hilltops.^[28] In contrast, the quantity of soil moved by tillage is independent of field size and leads to rapid soil loss at upslope field boundaries. Since erosion rates are generally considered in terms of mass per unit area, the amount of soil “eroded” by tillage is much greater on narrow fields than on long slopes.^[19,23,29] Thus, the more strips into which a field is divided, the greater the contribution of tillage translocation to terrace formation, and the more rapid terrace formation will be.

ENGINEERED TERRACES

Engineered terraces are designed to manage runoff from a certain contributing area. Therefore, when a field is to receive more than one terrace, it is common practice to start at the top of the field and work down so that the bottom terrace does not get overloaded by a storm that might occur before upslope terraces are completed. While specialized equipment such as bulldozers and scrapers are generally used for terrace construction, ordinary farm machinery can also be used to form broad-base terraces,^[30] and proper tillage operations are needed as part of routine maintenance to preserve functionality of all terraces.^[8]

Fig. 1 Patterns of erosion and deposition created by tillage and water erosion and deposition in a field near Coffeeville, Mississippi, U.S.A. Tillage translocation leads to erosion downslope of each grass hedge, creating the negative lynchets, while deposition due to tillage and water transport reinforces the positive lynchets.

Bench Terraces

For deep soils, tillage translocation can be used to reduce the cost and increase the farmability of bench terraces. On irregular fields, starting at the bottom of the slope may facilitate efficient development of straight parallel terrace systems. First, a bulldozer pushes up soil from below into a terrace with extra height where it crosses existing gullies.^[31,32] A tile outlet near the thalweg drains impounded runoff, leaving sediment trapped in the low area. When the thalweg area is sufficiently filled (up to 5 m of fill in 3 years), further sediment is cut off by construction of the next upslope terrace, parallel to the first. In one case, downhill moldboard plowing between terraces accounted for 50% of the soil moved, reducing a slope from 14% to 4% over a 15-year period. Similar to the natural development of lynchets that occurs when tillage is performed between strips of permanent vegetation, bench terraces can be developed by soil moved by tillage operations. Tillage smooths the benches, and the vegetation conserves soil and water while benches gradually develop.

A similar process occurs when fields are tilled between parallel vegetated strips, as described with reference to lynchets. The vegetation conserves soil and water while benches gradually develop. This process has been formalized by the U.S. Department of Agriculture–National Resources Conservation Service (USDA-NRCS) in the vegetative barrier national conservation practice standard.^[33] The vertical interval between vegetated strips should not exceed 2 m, and the planned vegetated back slope should not be steeper than 1 on 2, horizontal to vertical, which is consistent with historical practice.^[8]

Gradient Terraces

Gradient terraces are ridge-and-channel systems that reduce erosion by intercepting surface runoff and redirecting it to a stable outlet at reduced velocities. Tillage adjacent to vegetated strips may create small berms that form when soil is thrown beyond the implement width into and against the vegetation and deposited next to it and within it, later coalescing into a stable ridge. If the tillage boundary remains unchanged, subsequent operations increase the berm height until soil cannot be thrown atop the berm. When the vegetated strip deviates from the contour, these tillage-induced channels can act as gradient terraces and divert an appreciable fraction of runoff.

A microtopography survey was conducted at 28 locations along the upslope edge of several grass strips in a field with 6–9% slope steepness,^[25] farmed with tandem disks and chisel plows. At every location, asymmetrical triangular channels (Fig. 2) formed during seven years of commercial farming. The hydraulic radius of the smallest channel was 0.04 m. At 0.2% grade and Manning's $n = 0.025$, this smallest channel could carry 25 mm/hr of runoff from a 15-m wide cropped strip more than 100 m long. Since the

Fig. 2 Typical channel cross sections observed after several years of tillage with disks and chisel plows. When vegetated strips deviate slightly from the contour, small channels can act as small gradient terraces and divert an appreciable fraction of the runoff.

distance between local depressions in the field is usually less than 200 m, these tillage-induced channels could divert most of the fields' runoff to these depressions, where a stable outlet could be provided. Reducing downslope runoff accumulation interrupts slope length and reduces soil erosion by water.

A more detailed study showed that when tillage was conducted with tandem disks and chisel plows immediately adjacent to the vegetation, berms quickly formed along grass hedges planted close to the contour at the bottom of experimental plots with 22.1 m long, 5% slopes.^[27] Four years after tillage adjacent to hedges had begun, berms of triangular shape attained an average height of 0.13 m (Fig. 3), forming a shallow channel in the upslope side of the vegetation that diverted runoff. Observations indicated when no soil berm was present, most (>95%) runoff passed through grass hedges planted on 0.3% gradient from a true contour. Once tillage berms were formed, however, runoff from small storms no longer crossed the vegetation but was diverted to flow along the upslope side of the berm and grass hedge. The resulting berms diverted more than 70% of runoff from runoff events less than 10 mm/day and more than 55% for events less than 80 mm/day.^[34]

Tillage berms may or may not form, depending on the design and adjustment of tillage tools, which affect how soil is displaced to the sides. When soil is thrown beyond the implement's width, a line of deposition is created; if soil is moved away from the boundary, a dead furrow is formed. The presence of a grass hedge or other fixed boundary ensures that the position of the first pass near the boundary is maintained, facilitating the formation of berms or furrows. Tillage implement type and speed, slope steepness, and the superposition of sequential tillage operations determine the formation of berms and their dimensions. On flat lands, the creation of dead furrows

Fig. 3 Evolution of topography in the lowest 4 m of research plots with grass hedges and an average contributing area steepness of 5%. Chisel and disk tillage was kept a distance away from hedges from 1996 to 2000 and was moved adjacent to the hedges from 2001 to 2004.

and ridges associated with the layout of lands used to till the fields makes the tillage patterns clearly visible in light detection and ranging topographic data^[35] and can greatly alter surface hydrology.

TERRACE BENEFITS AND PROBLEMS

Bench terraces facilitate contour farming operations. On very steep slopes, mechanical cultivating is difficult, and contour plowing can be dangerous due to the risk of overturning. The formation of bench terraces reduces the slope steepness and therefore makes contour tillage easier and safer. When tractor or animal power is limited, it may be easier to plow or hoe downhill.^[11,29] However, when sufficient power is available, it is most efficient to plow on the

contour because a uniform load can be matched to a tractor or team of animals.

Contour tillage reduces runoff and soil erosion, thereby conserving plant nutrients and making more water available to grow crops.^[36] On the other hand, large fertility differences can develop between the negative and positive lynchets.^[12,19,24] This reduces uniformity of crop growth where fertilizer and liming amendments are not available. In these situations, farmers often cut soil from the terrace back slope and distribute it on the degraded negative lynchet. If the upper field is owned by a different landowner, an entire terrace may be undermined in this fashion.^[12] Manuring, fertilization with seaweed, and liming with marl were ancient responses to similar problems.^[37]

While tillage berms acting as gradient terraces can improve soil conservation where runoff is diverted to a

Fig. 4 Runoff reaching (A) a filter strip/riparian forest buffer surrounding an oxbow lake in the Mississippi Delta was (B) redirected by a small tillage berm to (A and C) a riparian ephemeral flow channel. Storm flow through this channel was controlled by (C and D) a slotted-inlet pipe and associated earthen pad, which created backwaters that allowed the riparian buffer to function.

Source: From Dabney, Moore, et al.^[38]

stable outlet, they can have negative consequences on the effectiveness of some conservation practices. For example, if berms keep a significant fraction of runoff water from entering a grassed waterway, erosion on the margin of the waterway may be increased. Tillage berms may keep water from entering a vegetated filter strip on very flat fields (Fig. 4), which may preclude the filter from improving water quality from small runoff flows. This problem is the main reason why the USDA-NRCS restricts the establishment of filter strips to fields with an upslope contributing area steepness greater than 1%.^[39] Tillage berms are also implicitly recognized in the USDA-NRCS contour buffer strip standard^[40] that states, "If sediment accumulates just below the upslope edge of the buffer strip to a depth of 6 inches or more ... relocate the buffer/cropped strip interface location."

CONCLUSION

Tillage erosion has come to be recognized as an important contributor to the evolution of agricultural landscapes and, in some cases, the degradation of soil resources. With each tillage operation, a tilled area becomes flatter, and some soil leaves the tilled zone in the form of clods deposited along field borders. Over time, these clods, along with stones removed from the tilled area and sediment deposited by runoff, coalesce to form terraces or lynchets. If a field is divided into several tilled strips, then the consequence will be the gradual development of bench terraces, unless the untilled areas are periodically relocated. Also, tillage-induced berms located at the upslope edge of the untilled areas may act as small gradient terraces that alter runoff flow patterns. On flat lands, tillage berms may dominate surface drainage patterns. The formation of such bench and gradient terraces due to agricultural tillage operations may or may not be desirable but can hardly be avoided, if field boundaries on sloping lands are fixed for long periods of time.

Tillage: Gas Exchange

Donald C. Reicosky

North Central Soil Conservation Research Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Morris, Minnesota, U.S.A.

Abstract

Concern for soil productivity and greenhouse gas emissions requires new knowledge to minimize agriculture's impact on the environment. Soil carbon is the foundation of a healthy environment and sustainable agriculture. This is highly dependent on management decisions that influence the intensity of tillage and the amount and placement of residues. Conservation tillage or no-till systems have shown increases in soil organic matter within 10 to 12 years of consistent use. The increase in soil organic matter depends on a delicate balance between the residue inputs of the previous crops and the tillage intensity associated with establishing the next crop. Farmers are faced with serious decisions with respect to environmental consequences of maintaining sustainable production and managing this delicate balance.

INTRODUCTION

Agriculture is the economic foundation of rural America and has a major influence on components of industry, world trade, and global ecology. In traditional agricultural production, tillage of the soil has been an integral part of the production process. Tillage is the mechanical manipulation of soil and crop residue to prepare a seedbed where crop seeds are planted, sprout, take root, and grow into plants to produce grain. Intensive tillage loosens soil, buries crop residue, enables the soil to warm and dry, enhances the release of soil nutrients for crop growth, kills the weeds that compete with crop plants for water and nutrients, facilitates root growth in compacted soil, and improves the flow of water and air within the soil. The enhanced gas exchange affects the processes that impact the accumulation and loss of soil carbon (C) in agricultural systems. Tillage increases water infiltration and increases the soil porosity, especially large pores, which allows greater movement of soil gases through the soil. Diffusion allows movement of gases into or out of the soil from higher to lower concentrations.

Concern for environmental quality and tillage-induced greenhouse gas emissions [carbon dioxide (CO₂), methane, nitrous oxide] requires new knowledge to minimize agriculture's impact on the environment. In the United States, the moldboard plow has been a significant symbol of agriculture over the past years and is being reevaluated in many parts of the world as new conservation tillage techniques are developed and researched.

CROP PRODUCTION AND SOIL C LOSS

The link between global warming and atmospheric CO₂, a greenhouse gas, has heightened interest in soil C storage, as

soil organic matter, in agricultural production systems. Agricultural soils and agricultural production play an important role in C sequestration or storage and thus can help mitigate global warming.^[1] Intensive tillage has mineralized or oxidized 30% and 50% of the native soil C or soil organic matter since the pioneers brought the soils into cultivation. Tillage processes and mechanisms leading to C loss are directly linked to soil productivity, soil properties, and environmental issues.^[2] Soil C dynamics can have an indirect effect on climate change through net absorption or release of CO₂ from soil to the atmosphere in the natural C cycle. In agriculture, C comes into the system through photosynthesis and is returned to the atmosphere as CO₂ through human and microbial respiration. Good soil C management is vital because of its role in maintaining soil fertility, physical properties, and biological activity required for food production. Good soil C management is also needed to partially offset greenhouse gas emissions from manufacture and use of acid fertilizers, liming, fossil fuels, and the release of more potent nitrous oxide and methane from agricultural systems. Minimizing agriculture's impact on the global increase of CO₂ requires that we sequester and maintain high C levels in soil.

TILLAGE-INDUCED CO₂ LOSS

Tillage affects soil microbial activity, organic matter decomposition, and soil C loss in agricultural systems. Much of the C is lost as CO₂, which is the end product of microbial feeding on soil organic matter. Reicosky and Lindstrom^[3] showed major short-term gaseous loss of C, immediately after tillage, which partially explains long-term C loss from tilled soils. Gas exchange was measured using a large, portable chamber to determine CO₂ loss from

various types of tillage. Moldboard plow was the most intensive tillage and caused more CO₂ loss than less intensive tillage methods. No till or no soil disturbance lost the least amount of CO₂, suggesting minimal environmental impact. Moldboard plowing loosens and inverts soil and allows rapid CO₂ loss and oxygen entry. It also incorporates and mixes residues to enhance microbial decomposition and respiration (oxidation).^[4] Stirring the soil in tillage is analogous to stirring the coals in a fire. Plowing accelerates microbial decomposition and soil aggregate breakdown to cause decreased soil C content in the surface layer. Ellert and Janzen^[5] and Rochette and Angers^[6] found similar results for different soils and less intensive tillage methods.

Reicosky^[7] reported that average short-term CO₂ loss from four conservation tillage tools was 31% of the CO₂ from the moldboard plow. The moldboard plow lost 13.8 times more CO₂ as the soil not tilled, while conservation tillage tools averaged about 4.3 times more CO₂ loss. The smaller CO₂ loss from conservation tillage tools was significant and suggests progress in equipment development for enhanced soil C management. Conservation tillage reduces the extent, frequency, and magnitude of mechanical disturbance caused by the moldboard plow and reduces the large air-filled pores or holes in the soil to slow the rate of gas exchange and C oxidation.

Strip tillage tools are designed to minimize soil disturbance. Different strip tillage tools and moldboard plow were compared to quantify short-term tillage-induced CO₂ loss relative to tillage intensity.^[8] Less intensive strip tillage reduced soil CO₂ losses. No till had the lowest CO₂ loss, and moldboard plow had the highest immediately after tillage. Forms of strip tillage had an initial soil CO₂ loss related to tillage intensity intermediate between the extremes of plowing and no till. The cumulative CO₂ losses for 24 hours were directly related to the soil volume disturbed by the tillage tool. Reducing the volume of soil disturbed by tillage should enhance soil and air quality by increasing the soil C content and suggests that soil and environmental benefits of strip tillage be considered in soil management decisions. The CO₂ released immediately after moldboard plowing suggests little C sequestration. Conservation tillage methods that leave most of the crop residue on the surface with limited soil contact yield better C sequestration to enhance environmental quality.

MECHANICS OF GAS EXCHANGE

Tillage affects all physical soil conditions, especially aeration.^[9] Tillage can drastically change the configuration, continuity, and size of soil pores. The moldboard plow is probably the most efficient implement to loosen a large volume of soil and to break up dense, massive soil clods into smaller units. After plowing, all plants and plant residues are buried and partially mixed into the soil, simplifying subsequent tillage and planting operations.

Several tillage-related factors affect soil gas exchange, especially the soil porosity and air permeability. The exchange of air between the soil and the atmosphere is bidirectional and can occur by two different mechanisms called diffusion and convection. In diffusion, the moving force is the gradient of partial pressure or concentration of the specific gas that causes the unevenly distributed molecules to randomly migrate from a zone of high concentration to low concentration. In convection, also called mass flow, the moving force consists of a gradient of total gas pressure and results in the entire mass of air streaming from a zone of high pressure to a zone of low pressure. Barometric pressure changes, soil temperature gradients, and wind gusts over the loosened soil surface can create pressure differences between soil air and the external atmosphere, thereby inducing convective flow into or out of the soil. Whether diffusion or mass flow is the dominant gas flow mechanism from soil depends on the total pressure gradient and pore size and pore continuity. When the soil is consolidated with only small pores, gas exchange can occur primarily by diffusion. When the soil has large pores, gas exchange can also occur still by mass flow. Out in the field, both processes are occurring simultaneously.

The degree to which air pressure fluctuations and convective flow can exchange gas between soil and the atmosphere has long been debated among soil physicists. Most believe that diffusion, rather than convection, is the more important gas exchange mechanism. Available evidence suggests that convection can, in certain circumstances following intensive tillage, contribute significantly to gas exchange and soil aeration, particularly at shallow depths and in soils with large pores.^[10] The tillage-induced CO₂ loss demonstrates the role of mass flow as a cause of C loss from tilled soils. The magnitudes of CO₂ fluxes were too large to be accounted for by simple diffusion from the soil.^[3] The tillage-induced change in soil air permeability showed that convection contributes significantly to gas exchange.^[11]

While the effects of mass flow are intermittent and variable, they tend to be particularly significant immediately after a tillage event up to the time that the soil reconsolidates. External factors that cause soil reconsolidation may include secondary tillage, raindrop impact, or wheel track compaction. The real concern follows an intensive tillage operation, where the change in the soil physical properties increases soil air permeability and changes the gaseous loss from a diffusion-controlled process to a convectively controlled process. Methods for measuring change in soil air permeability on large scales have not been developed.

SOIL PRODUCTIVITY AND ENVIRONMENTAL BENEFITS

While moldboard plowing and other forms of intensive tillage have done much to increase U.S. crop production

over the past years, the increase in production has been accompanied by unseen costs of decreased soil quality from erosion and increased greenhouse gas emissions.^[1,12] The organic matter of many of the prairie's soils has declined from that present under virgin conditions. The unseen, unmeasured costs that result from intensive tillage include loss in soil C due to enhanced oxidation and depletion of soil fertility reserves. The magnitude of these unseen costs depends primarily on the intensity of tillage, the quantity and quality of crop residue returned to the soil, and the crop rotation. Intensive tillage, primarily moldboard plowing, decreases soil C in virtually all crop production systems.

CONCLUSION

Concern for soil productivity and greenhouse gas emissions requires new knowledge to minimize agriculture's impact on the environment. Soil C is the foundation of a healthy environment and sustainable agriculture. This is highly dependent on management decisions that influence intensity of tillage and the amount and placement of residues. Conservation tillage or no-till systems have shown increases in soil organic matter within 10 to 12 years of consistent use. The increase in soil organic matter depends on a delicate balance between the residue inputs of the previous crops and the tillage intensity associated with establishing the next crop. Farmers are faced with serious decisions with respect to environmental consequences of maintaining sustainable production and managing this delicate balance.

Tilth

Jerry L. Hatfield

National Laboratory for Agriculture and the Environment, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Ames, Iowa, U.S.A.

Abstract

Soil tilth has and continues to be an interesting term. The term intrigues people because of its connection with the soil and confuses people because of their inability to provide an exact definition or measurement of the concept. As a term that describes a soil property, it is better visualized than quantified; however, the biological, chemical, and physical principles that underlie tilth are fundamental to a quality soil resource. Soil tilth has potential agronomic, biological, and engineering aspects that further increase the richness of being able to understand the dynamics of the soil.

Tilth embodies the fundamental understanding of soil structure changes in response to tillage, organic matter additions, and crop rotations. Soils will not respond the same to different inputs and management practices because of fundamental differences among soils in their basic composition of sand, silt, and clay. Improving tilth will benefit the water exchange, gas exchange, nutrient cycling, and ability of a plant to explore the profile, support the biodiversity of biological system in the soil, and provide the structural support for land management operations. The dependence of humankind on the soil as a source of food requires that we begin to understand how to manage our soils for their long-term improvement and enhancement.

INTRODUCTION

Tilth describes the physical attributes of the soil but is more than a description of the physical properties. Tilth is more of a description of the properties that describe its ability to support plant growth, biological processes, and exchange processes and provides a stable base for engineering applications. This entry explores the history of the concept of tilth and its measurement, the role of tilth in the functions of the soil, and the potential for the improvement of tilth. Understanding these processes will help us understand the value of soil as a critical resource for the future of humankind.

HISTORY OF TILTH

One of the first references to tilth was provided by Keen.^[1] He provided a summary of previous observations regarding the importance of tilth for the planting of crops into the proper seedbed, the impact of frost on the soil, how hard rains after plowing would create a crust, and how grazing animals could compact the soil. It is interesting that through his observations, he gleaned information that described the biological, chemical, and physical responses of soil to various forces. Keen's treatise on the physical conditions of the soil was followed by a paper by Yoder^[2] who described soil tilth as the soil conditions that determined the "fitness" of the soil for the growth and development of crop plants. The cornerstone of his definition of tilth was based on soil structure. Yoder^[2] defined the ideal tilth as offering minimum resistance to root penetration; allowing for good infiltration

and storage of soil water; having a good exchange of gases between the soil and the atmosphere with adequate air supply in the soil; having the proper balance of water and air in the pore space of the soil; resisting erosion; promoting microbiological activity; facilitating the placement of green manure crops and organic residues; and providing a stable foundation for farm implements. This is a very inclusive list that covers all aspects of the functions of soil but more importantly demonstrates the potential interaction among the physical, biological, and chemical processes that are occurring within the soil. Yoder recognized and emphasized the value of green manure crops and organic residue addition to the soil, as one of the key components in the development of tilth. There were other very early observations that soil organic matter (carbon) in the upper soil surface declined as a result of tillage operations. Whiteside and Smith^[3] reviewed the literature and found tilled soils had less organic matter than untilled grasslands or forest areas. The change in organic matter in soils is shown in Fig. 1 and shows that the state of organic matter content is near steady state. There are efforts underway to potentially increase organic matter in soils through the use of conservation tillage systems coupled with manure. These practices are based on the observations that were detailed in how to increase the tilth of the soil in the 1960s.

Yoder^[2] also made another interesting observation in which he found that poor soil tilth was associated with soil structure because factors that cause problems with stable soil structure were the same as those that caused problems with tilth. Soil structure is a critical component of soil tilth and cannot be overlooked in the process of how to

Fig. 1 Schematic representation of changes in soil organic matter as native soil is subjected to cultivation.

improve soil tilth. Changes in soil structure and the impact on soil tilth are probably most quickly recognized by gardeners because they work their soil either by hand or with small tools where the effect of improving soil tilth is readily apparent, and hard soil requires more energy to prepare and produces less vigorous plants.

IMPROVEMENT OF SOIL TILTH

Karlen et al.^[4] summarized the literature on soil tilth and proposed several areas for potential research on soil tilth. They suggested that an examination be made of the tilth-forming processes as a combination of physical, chemical, and biological processes that interact within the soil. They proposed a definition of tilth as “The physical condition of a soil described by its bulk density, porosity, structure, roughness, and aggregate characteristics as related to water, nutrient, heat, and air transport; stimulation of microbial and microfauna populations and processes; and impedance to seedling emergence and root penetration.” This is an inclusive definition that illustrates the major factors affecting soil tilth; however, the impact of these different factors can only be realized as the result of complex interactions between the basic foundation of soil, i.e., sand, silt, and clay particles, and the biological, chemical, and physical forces that create a stable soil aggregate. Creating soil tilth requires time because these processes carry the additional element of time for them to exert their impact on the soil. There is a large hysteresis effect in that it takes little time to degrade soil but a much longer time to enhance soil. Another dimension to this problem is that not all soils will respond the same to the addition of organic material through either plant roots or manures and there needs to be an increased understanding of how cropping systems interact with tillage across soils and climates to quantify the impacts on tilth. Manure and organic amendments remain the most effective additions to soil to begin the pathway toward enhancing the soil.

ROLE OF SOIL TILTH

Good soil tilth provides a stable base for agricultural production. The ability of a plant to explore the soil profile to extract water, nutrients, and oxygen reduces a potential limitation to plant growth. A limited soil profile equates to a limited amount of plant growth and less vigorous plant. The vast majority of the world’s agriculture depends upon rainfall to produce a reliable supply of food, feed, or fiber. When the soil has an unstable structure that easily crusts, infiltration of rainwater into the soil is limited. This is critical when rainfall occurs in intense storms. The other limitation comes when soil water-holding capacity is diminished by reductions in organic matter and the rainfall leaches through the profile and is not available to the plant. The simple change in the soil creates a limitation to plant growth and yield because of reduced water availability. Fields with poor soils often show poor plant growth because of water limitations even in years that have normal rainfall for that location. Efficient use of stored soil water is critical to providing food, feed, and fiber for the world’s population, and the process begins with a soil that has good tilth. Soil with good tilth has improved nutrient cycling because of the role of soil organic matter nurturing microbiological activity within the soil and supplying nutrients to plants is as critical as water for sustaining plant productivity.

There are also indirect effects of soil tilth on plant production systems that are often ignored. Healthy soils with good tilth have fewer pressures on plants from insects and diseases. This aspect has not been fully studied but offers an additional piece of evidence for the proper management of the soil resource.

It is critical to consider soil tilth as part of the ecosystem that contributes to improved ecosystem health and ecosystem services, e.g., water quality, air quality, biodiversity, and efficient use of resources. Soil is a foundation for the existence of humankind; however, good soil tilth increases the value of that foundation to provide a reliable source of food, feed, fiber, and fuel from the soil. Soil is precious, and good tilth increases the value of the soil for all future generations.

Abstract

Soils vary greatly in their characteristics and potential to meet human needs. The most essential function of soil from a human perspective is that soil serves as the reservoir of water and nutrients essential for sustained plant growth. Plants serve as our food, either via direct production of fruit, vegetables, and grain or indirectly as feed for livestock. Soils also serve as the foundation for societal infrastructure and as a medium for the disposal and amelioration of wastes. The regional and global differences in soil characteristics and potentials for use are due to differences in energy fluxes in the various ecosystems of the world. The objective of this entry is to discuss the evolution of soils as a function of time and factors that result in the spatial distribution of the multitude of soils that mantle the earth.

INTRODUCTION

Soil, the relatively thin organic-mineral entity at the earth's surface, forms at the interface between the atmosphere and lithosphere by the assimilation of energy. The sun not only warms the earth's surface which increases the rate of chemical reactions but also drives the photosynthetic production of biomass. Death and decay of biomass result in the accumulation of humus in the upper horizon(s) of soil. Soil formation is also driven by the weathering of minerals in the lithosphere which releases energy utilized in soil development and nutrients that are essential for the growth of plants. Gravitational energy provides the driving force for the infiltration and percolation of water into and through the earth's surface. The magnitude of humus accumulation, mineral weathering, and translocation or leaching of solutes and colloids by water moving through the lithosphere plays a major role in differentiating the great diversity of soils that cover the face of the earth.

SOIL EVOLUTION AND DEGRADATION AS A FUNCTION OF TIME

Soil formation is initiated the moment a portion of the lithosphere is exposed to the atmosphere following major depositional or erosional geologic events. The geologic materials deposited by water, wind, ice, or gravity or exposed by erosion are referred to as "parent material" because they are the precursor of soil. Common parent materials are alluvium, glacial till, glacial

outwash, lacustrine and marine sediments, Loess (wind-blown silt), volcanic ash, pedisegment, colluvium, and residuum (weathered bedrock). Very youthful soils differ little from their parent material but as time progresses, soils with characteristics distinctive of the ecosystems in which they form will evolve (such soils are considered mature soils). The evolution of a youthful to a mature soil proceeds due to additions and losses of materials and translocation and transformation of components within the soil.^[1] Specific processes include the weathering of primary minerals to secondary minerals (clays, salts, and oxides) and soluble ions, leaching of soluble components from the soil, accumulation of organic matter in the soil, and the translocation and accumulation of secondary minerals within the soil. All of these processes contribute to the formation of unique sequences of soil horizons characteristic of the various mature soils.

Young soils exhibit weak expression of horizons, little accumulation of organic matter above that in the geologic parent material, and minimal mineral weathering. Such soils generally exhibit only A and C horizons (lack B horizons) and classify as Entisols in *Soil Taxonomy*.^[2] With additional time, such soils will develop weak B horizons, become more intensely weathered, and accumulate organic matter. These developments will qualify the soils as Inceptisols in *Soil Taxonomy*.^[2] Eventually as weathering and developmental processes continue, a mature soil will form. A mature soil can be defined as a soil that has attained a steady state with the energy fluxes in the ecosystem in which it occurs. This implies that there are sufficient energy influxes from the

ecosystem to maintain the soil in its state for an indefinite time but insufficient energy for additional soil formation. Most of the soil orders in *Soil Taxonomy* represent such steady states. The distribution of these mature orders will be discussed in the second section of this entry.

Rates of soil formation are a function of the ecosystem in which soil formation occurs and the existing stage of soil development. Soil formation occurs more rapidly in high energy ecosystems (tropical) and in youthful, relatively shallow soils. As soil formation progresses toward maturity, increases in soil depth gradually slow and eventually cease because weathering, leaching, and energy inputs are reduced at depth. Buol et al.^[3] list soil formation rates, obtained from the literature, ranging from 0.1 to 750 yr/cm; the former at the surface of a recent mudflow and the latter at a depth of 1 m in an Oxisol. Although rudimentary soils can form in <100 years, thousands of years are necessary for mature soils to form. Because more time is required to acquire the energy necessary for intensely weathered and/or highly developed soils to attain maturity, soil orders can be arrayed by the amount of time required to attain a steady state (Fig. 1). The steady-state condition attained by mature soils necessitates that such soils are being regenerated at the same rate as they are being degraded by weathering or truncated by geologic erosion. Troeh et al.^[4] suggest “a rate of 1 mt/ac yr may be considered typical for geologic erosion from gently sloping soils.” Using this geologic erosion rate, a steady-state condition could be maintained with a rate of soil formation of 100 yr/cm of soil.

Accelerated erosion caused by human activities on the landscape, however, can remove soil at rates that are many times that of the capacity for soil regeneration. Whereas maximum “tolerable” soil loss rates have been established at 11 mt/ac yr by the U.S. Department of Agriculture—Natural Resources Conservation Service (10 times the rate of geologic erosion), accelerated erosion rates exceeding 450 mt/ac yr have been documented.^[4]

Fig. 1 Schematic diagram showing the variations in time to attain the steady state for various soil orders.

Source: From Birkeland.^[5]

Wischmeier and Smith^[6] defined tolerable soil loss as “the maximum level of soil erosion that will permit a high level of crop productivity to be sustained economically and indefinitely.” It is obvious that mismanagement of soils can result in the loss of soil at a rate greater than that of soil formation.

Reduction of the world’s soil resources poses a serious threat for the longevity of humankind. Accelerated erosion is not the only process leading to soil degradation; compaction, oxidation of organic matter due to tillage and drainage, and salinity due to poorly managed irrigation systems all contribute to soil degradation. On the basis of the rate of soil formation relative to the length of a human lifetime, soil must be considered a non-renewable resource. Soil loss due to accelerated erosion will not be regenerated in our lifetime. Degradation of the quality of soil due to inappropriate management practices, however, can be reversed by the use of best management practices; thus, soil can be considered a renewable resource with respect to soil quality. The most unique attribute of soil is that soil can be used indefinitely without deterioration if managed for sustainability.

SPATIAL DISTRIBUTION OF MATURE SOILS

Soil results from the interactions among climate, vegetation, geological parent material, topography, and time. These five “state factors,” as formulated by Jenny,^[7] determine the nature and distribution of soils over the face of the earth. The relative importance of a given state factor’s influence on soil properties is a function of scale. Climate is generally the most important state factor at a global scale, whereas vegetation is the most important factor at a regional scale. At a local scale, topography and parent material separately or in combination often control the distribution of soils.

Precipitation and temperature are the most important climatic factors controlling the weathering and, ultimately, global distribution of mature soils (Fig. 2). Warm, wet climates generally result in highly weathered soils, whereas dry, cold climates result in minimally weathered soils. Climates between these extremes result in the formation of soils with intermediate degrees of weathering. This relationship can be illustrated by considering a few major climatic areas of the world. Wet tropical regions such as the rainforests of the Amazon Basin of South America and the Congo Basin of Africa are noted for deep, highly weathered, nutrient-poor soils classified as Oxisols in the U.S. soil classification system.^[2] Many Oxisols, however, occur in dry climates as relicts of paleotropical climates. Oxisols are often red in color due to the concentration of iron and aluminum oxides, as other chemical components are released by weathering and leached from the soil. On the opposite end of this spectrum, the polar regions of North America, Europe, and Asia have

Fig. 2 World soil map.

Source: From USDA–NRCS.^[8]

large areas of Gelisols,^[2] which are permanently frozen soils. Because little weathering occurs when a soil is frozen, Gelisols are generally minimally weathered soils. Both Gelisols and Oxisols very readily degrade due to mismanagement but for contrasting reasons. Gelisols are fragile because they develop and regenerate at such an exceedingly slow rate. Oxisols are so highly weathered that they are depleted of primary minerals and nutrients; thus, there is little internal energy remaining for regeneration.

On progressing from humid-tropical to humid-temperate climates, soils generally become less weathered. The following soil orders can be considered a weathering continuum: Oxisols (tropical)–Ultisols–Alfisols (temperate). Ultisols generally occur in humid, temperate to semitropical climates, but may also occur in wet tropical locations where there has been insufficient time for Oxisols to form. Ultisols are concentrated in Central America, the southeastern quadrant of the United States, Asia, and Africa. The key properties of Ultisols are low-nutrient and nutrient-bearing mineral contents, an A horizon with low organic matter content, and a thick, prominent B horizon. The B horizon is a zone of clay concentration due to both clay illuviation and formation. Alfisols are found in humid-temperate climates (with deciduous forests) that are too cool for

Ultisols to form. These regions include much of eastern North America, Central Europe and Great Britain, and China. Alfisols are more fertile and contain more nutrient-bearing minerals than Ultisols due to less intense weathering. Alfisols are also characterized by clay accumulation in B horizons, but the accumulation is less pronounced than in Ultisols. In addition, the clay accumulation in Alfisols is more dependent on clay illuviation and less dependent on clay formation than that of the B horizons in Ultisols.

Wet and/or cool climates such as in Scotland and Ireland result in the formation of Histosols.^[2] Histosols are organic soils developed in wet, anaerobic locations where plant production of organic matter far exceeds decomposition of the litter produced. Histosols can be tens of meters deep, although they are generally 1–3 m deep. They are commonly referred to as peats and mucks. Historically, these soils have been mined for use as fuel. The arid and semiarid climates of the world result in the presence of either Aridisols or Entisols.^[2] Aridisols and Entisols in arid regions cover nearly 28% of the globe due to extensive dry areas in Africa, North America, South America, Asia, and Australia. Aridisols range from moderately developed soils that are relicts of past more humid climates to weakly developed soils

commonly containing soluble salts due to minimal leaching. Such diverse soils are grouped together as Aridisols primarily due to sufficient moisture for only very limited vegetative growth without irrigation. Entisols, which commonly consist of shifting sands and consequently show very little soil development, dominate the driest portions of the earth's surface. Entisols also occur in other climatic regions on very young or weathering resistant parent materials.

Vertisols^[2] are very clayey soils associated with seasonally wet and dry climates. They are widespread in western India, eastern Australia, and along the northwestern coast of the Gulf of Mexico. During the dry season, Vertisols develop wide, deep cracks that swell shut during the wet season due to the expansive nature of the clays. The swelling pressures in the subsoil cause it to be thrust toward the surface resulting in heaving of the soil surface. Repetition of this cyclic process between seasons results in churning or inversion of the soil.

The distribution of vegetative communities is a function of climate, comparable to the impact of climate on the distribution of soils; however, vegetative communities superimpose unique soil forming processes and characteristics on those imposed by climate. This can be illustrated by considering the distribution of Spodosols, Alfisols, and Mollisols,^[2] which are strikingly different soils. Spodosols occur in ecosystems dominated by conifers (e.g., Maine and other northern New England states, Michigan, Wisconsin, Minnesota, and upper New York state), Alfisols occur in ecosystems dominated by deciduous trees (e.g., New York, Pennsylvania, and Ohio) and Mollisols in prairie ecosystems common throughout the Central United States (e.g., North Dakota to Texas and Illinois to Colorado). Spodosols are generally shallow, sandy, low fertility, and acidic soils characterized by a prominent bleached E horizon over B horizons that have accumulated iron and aluminum oxides and/or humic materials due to the chelation and translocation of these components by compounds released by the coniferous vegetation or decomposition products of the litter. Alfisols are fertile soils characterized by an A horizon with low organic matter content and clayey B horizons. The translocation of clay from near surface horizons to the B horizon is attributed to the high degree of acidity produced by the decomposition of the leaves of deciduous trees. Mollisols are fertile soils characterized by thick, dark, humus-rich A horizons that form in prairie ecosystems. The annual production of a deep, fibrous root system by prairie grasses in conjunction with the calcium-rich chemistry of the soils results in the accumulation of stable humic compounds in the soil to considerable depth.

The distribution of soils on a landscape scale is generally related to the distribution of vegetation, topography, and parent materials or a combination thereof. An example of vegetation determining soil distribution occurs in some Iowa landscapes where soils formed in deciduous forest,

savannah, and prairie ecosystems exist contiguously. Alfisols formed in the forested ecosystems, Mollisols in the prairie ecosystems, and soils with properties intermediate between Alfisols and Mollisols in the savannah ecosystem. Because of the causative relationship between ecosystem biology and soil pattern, such soil distributions are referred to as "biosequences."

The impact of parent materials on the distribution of soils occurs at any scale but is most evident on large scale maps. Sharpsburg, Lindley, Gosport, and Nodaway soil series form an association in the various parent materials that occur in the hilly landscapes of southern Iowa and northern Missouri (Fig. 3). The soils comprising this association are quite different as indicated by their classification into different soil orders: Sharpsburg derived from Loess is a Mollisol, Lindley derived from glacial till is an Alfisol, Gosport derived from shale is an Inceptisol, and Nodaway formed in alluvium is an Entisol. Although differences in age of the four parent materials influence the classification of soils at the order level, the soils derived from the different parent materials would classify as different soil series based solely on properties inherited from the parent materials.

Another parameter influencing soil distributions, especially at the field scale, is the impact of water flow, both surface and subsurface, in the landscape. Much of the precipitation that falls on sloping landscape components is removed by surface runoff, whereas depressional soils accumulate surface run-on and retain all precipitation. Potential water infiltration and percolation through the soils are, therefore, least on sloping landscape components, intermediate on level areas, and greatest in the lowest portions of the landscape. The depth to a water table (zone of saturation in the lithosphere) also varies across landscapes. The shallowest depth to the water table generally occurs in the lowest landscape positions which serve as the primary point for aquifer recharge, whereas, the greatest depths to the water table occurs in the landscape components with the highest elevations (Fig. 4). Due to differential water distribution and depths to water tables within landscapes, soil wetness and drainage classes vary within landscapes.

Fig. 3 Cross section of a landscape showing the relationship between soils and geological parent materials from southern Iowa and northern Missouri.

Fig. 4 Cross section of landscape showing relationship between soil distribution and topography, drainage class, and depth to seasonally high water table (undrained condition) in Morley–Glynwood–Blount–Pewamo association of western Ohio.

Wetness and drainage characteristics have a major impact on the suitability of soils for various uses, both agricultural and nonagricultural (construction, sewage disposal, home sites, recreational activities, etc.).

CONCLUSION

In summary, the world's soils are distributed in a highly systematic manner. Soil properties and distribution are predictable with knowledge of the five state factors and their impact on soil formation. Time is required for mature soils, those steady-state entities comprising the uppermost portion of the lithosphere, to evolve from geological parent material. The relative importance of the other four factors

is a function of scale. Climate and vegetation are most important in explaining global soil patterns, whereas parent material, topography, and time are more important at landscape scales.

Torrential Erosion: Himalayas

Ram Prashad Yadav

*Regional Center, National Bureau of Soil Survey and Land Use Planning,
New Delhi, India*

Abstract

Torrential erosion is an extreme case of accelerated erosion wherein a large mass of soil is detached from catchment/hill and is transported rapidly with large volume runoff through rainy seasons streams called torrents and deposited in torrent beds and low lying fields. Though of very short duration during monsoon season, it causes immense damage to life, property and the ecosystem in the Himalayan region of India, Nepal and Bhutan. Intense flash floods in Lower Himalayas (Ropar, Punjab state) in 1988 and Middle Himalayas (Kedarnath, Uttarakhand state) in 2013 are the most glaring examples of natural devastation that caused heavy losses of human lives, livestock and infrastructures beside land and vegetation. Both natural factors (geology, physiography, seismic activities, and torrential rains) and anthropogenic activities (population, deforestation, infrastructure construction, and unscientific cultivation on hill slopes) make the region susceptible to mass erosion. It is possible to delineate mass erosion prone areas based on geo-environmental factors in the Himalayan region. While land hazard zonation is an effective technique in Middle and Upper Himalayas, vulnerable Shivalik/Lower Himalayan regions can demarcated based on a single value stability indicator. Amelioration techniques for treatment of mass eroded areas are very costly and require large investments for vast areas. A three-pronged integrated participatory approach comprising of catchment area treatment, torrent control measures, and rehabilitation of torrent beds and adjoining fields has proved effective for sustainable management of the fragile ecosystem. Central and state governments have implemented many projects with internal resources and external funding to check the menace of torrential erosion.

INTRODUCTION

Torrents are mountain streams that flow with high velocity and are flashy, usually carrying large size bed load particles. They transport heavy loads of sediments derived from landslides, landslips, or other unstable areas. Typically, torrents occur in the valleys of steep, small catchments or watersheds that experience periods of torrential rainfall and are susceptible to extensive and rapid soil erosion from the landscape. In Nepal, these are described as debris torrents as they involve rapid movement of water charged soils, rocks, and organic materials down steep slopes. In India, torrents have various local names and are known as “*choes*” in Punjab and Haryana, “*kholas*” in Himachal Pradesh and Nepal, “*Jhora*” in Sikkim and West Bengal, and “*Dong/Jhora*” in Assam and Bhutan.

In India, torrents have been taken as small mountainous rainy season streams rushing down the slope with flashy floods, often loaded with sediments. Typically, perennial streams fed by the melting of snow are not considered torrents. Flash floods in the torrents during peak storms in the rainy season (four to five times in a year) cause severe problems of land erosion and floods in the command area. The floodwater, about a meter or so in depth, comes

all of a sudden, and though it lasts for 2–3 hours only, causes immense damage to land, vegetation, and infrastructures.

TORRENT VS. TORRENTIAL EROSION

Though torrents and torrential erosion are two different terms, they are often but erroneously used synonymously. Torrential erosion describes the complete process of erosion (detachment, transportation, and deposition) and includes all the areas affected by erosion in catchments, torrents, and land inundated by flash floods. Torrential erosion is an extreme case of accelerated erosion wherein a large mass of soil is detached from hills and a large volume of runoff laden with debris rushes down the hills and spreads in the plains leading to the formation of torrents. Thus, torrents are the valley streams that transport eroded materials from a fragile watershed that experience mass erosion through landslides, landslips, and land sledging during torrential rains. During transportation, these cause problems of channel flow, deposition, meandering/shifting of course, inundation of bank, etc., in their course. The genesis of torrents, damage caused by them, and their control measures have been documented by various

organizations like Food and Agriculture Organization^[1,2] and researchers.^[2,3] Aggradation and degradation in torrents is therefore just a part of torrential erosion. Thus, the taming of torrents in isolation without treating catchments is a futile exercise.

EXTENT OF EROSION IN HIMALAYAN REGION

The Himalayas extend from the Indus in the west to the Brahmaputra in the east. They form an arc between two extremes, covering a distance of 2500 km. From east to west, the width of the Himalayas varies from 150 to 400 km. The northern most ranges of the Himalayas have the highest peaks and are known as Greater Himalayas or Upper Himalayas. To their south lies the Middle Himalayas of intermediate heights. The southern most ranges are known as the Outer or Lower Himalayas and commonly referred to as the Shivalik ranges/hills. These occupy significant portion of Nepal, Bhutan, and the Indian states of Assam and West Bengal in the east and Jammu and Kashmir, Himachal Pradesh, Punjab, Haryana, and Uttarakhand in the west.

A major part of Greater and Middle Himalayas is either covered with snow or devoid of any soil (rock outcrops). The Shivalik Hills (Outer Himalayas) are composed of various strata of loose conglomerates beds, friable sandstone, siltstone, and claystone. In these regions, few showers of an intensity higher than 12.5 mm hr^{-1} account for 85% of the rainfall received during the four monsoon months (June to September), the main rainy season. The steep unstable slopes, torrential rains, fragile geology, and rapid deforestation make the Shivalik ecosystem most susceptible to torrential erosion.

Precise information about the extent of torrential erosion for the entire Himalayan region is not available. The National Commission of Agriculture compiled available information and obtained an estimate of 2.73 Mha in India.

GENESIS OF TORRENTIAL EROSION

Removal of protective vegetative cover favors gully formation, which expand toward the head horizontally and get deeper because of rapid movement of runoff water in high slopes. The deep gullies with steep side slopes promote mass erosion through landslides, landslips, deepening of channel bed, and bank caving in the fragile hills. Faulty construction of roads, railway tracks, building, and canals or uncontrolled mining also causes unstable hill slopes, which result in landslides. Thus, excessive debris loads are carried to hill torrents down below. Torrent development is closely related with landslides in the catchments. In Nepal, the watersheds producing torrents experience landslides produce an average soil loss of $38.3 \text{ Mg ha}^{-1} \text{ yr}^{-1}$. On the contrary, watersheds covered

with dense *Shorea robusta* forests, which do not experience landslides produced an average soil loss of $<1 \text{ Mg ha}^{-1} \text{ yr}^{-1}$, had no torrents downside.^[4]

Flashy floods laden with debris come rushing down the hill slope and develop into channels of large dimensions and with lower flow intensities. Because of the greatly reduced carrying capacity of the discharge in the channels located in the plains, coarse material gets deposited in gravel bars and isolated islands. As a result, the discharge tends to migrate laterally cutting the ill-defined banks of the channels, and creating meander patterns that are typical of streams, not totally confined by the valley walls. During extreme storms, the discharge is so large that it inundates low lying agricultural fields and deposits large amount of coarse sand and gravels. The torrent beds widen many times that needed to convey effective discharge or even large floods. Often a large number of torrents discharge into the main rivers causing flash floods. The Soan river, during its run of 55 km in Himachal Pradesh, is fed by about 73 torrents with combined catchment area of $1,204 \text{ km}^2$.

The magnitude of damage caused by flash floods depends on the intensity of rainstorm. In 1988, the Shivalik region of Punjab received 700 mm rainfall in 3 days in the last week of September and experienced severest form of flood. Beside extensive damage to standing crops, livestock, and infrastructures, large amounts of sand were deposited in the agricultural fields along 200-km long stretch from Chandigarh to Pathankot. The State government incurred an expenditure of 2.64 billion rupees to clear sand from worst affected area of 2,988 ha. Rainfall events on June 16 and 17, 2013 caused flooding of Saraswati and Mandakini rivers in the Rudraprayag district of Uttarakhand (Fig. 1). Prolonged heavy down pour on these dates resembled a “cloud burst” (except for amount of precipitation of 100 mm hr^{-1}) type event in the Kedarnath valley and surrounding areas

Fig. 1 Vast devastation caused by torrential erosion in Chamoli district, Uttarakhand state of India in 2013.

Source: From Anonymous.^[5] ©2013 Deccan Chronicle Holding Limited, Hyderabad.

that damaged the banks of river Mandakini for 18 km between Kedarnath and Sonprayag and completely washed away the towns of Gaurikund, Rambara and Kedarnath. The roads and footpath between Gaurikund and Kedarnath were also damaged.^[5] There were reports of loss of a large number of human lives and damage to the property and livestock.^[6]

CAUSES OF TORRENTIAL EROSION

Landslides in the Upper and Middle Himalayas and landslips/vertical cliffs in Lower Himalayas are mainly responsible for torrential erosion. A landslide is a downward movement of a mass of rock or soil as a result of slope failure. The main reason for landslide occurrence is gravity force involving failure of earth materials under shear stress, i.e., when the shear stress exceeds the shear resistance of soil mass. Natural factors like steep slopes, a fragile geology, high seismic activity, and good rainfall make the region highly susceptible to landsliding. The problem has been further aggravated by anthropogenic activities like deforestation, unscientific cultivation on steep slopes, and developmental activities like road construction, mining, and rampant building constructions on hill slopes.

Water seeping through disturbed slopes, toe cutting by rivers and torrents, and pore water pressure in the soil zone are major agents responsible for landslides. Torrents, especially in their early stages, because of excessive velocities of flow and turbulence carry out quick removal of debris and cutting of sides. The landslides mostly take place after heavy rainfall. Construction of roads with slope deformities also accelerate mass erosion in the hills. These roads have been observed to suffer from about 4 to 10 landslides and 8 to 20 slumps per km, engulfing an area of about 15–20 ha.^[7] Major landslides in the Himalayas are estimated to cause an annual loss of more than 50,000 man hours per km and 5,000 vehicle hours per km on hill roads due to disruption of communication alone. The country suffers a loss of Rs. 1.50 billion annually toward the cost of removal of debris from the roads and loss of vehicle hours.

Majority of the Himalayan region falls under the highly earthquake prone “Zone V,” where earthquakes of magnitude 8 or more on the Richter scale could occur. Cracks developed in the underground rock layers, following an earthquake, may result in landslides during a monsoon due to reduced shear strength of underground strata. The two fault lines passing across the Himalayan region, the main central thrust (MCT) and main boundary fault (MBF), have been active for the past 400,000 to 500,000 years and are responsible for the formation of new landslides near the region of these fault lines. Chamoli and Uttarkashi fall on the MCT while MBF passes through Shimla–Dehradun–Almora.

Landslides are often caused by the cumulative effects of both natural and man-made factors. Landslides and

floods occurring in higher Central Himalayas of Chamoli district (Uttarakhand), which serve as the source for the Alaknanda river, have been attributed to inadequate vegetation cover coupled with the sheared carbonate rocks.^[8] Using remotely sensed data, the authors established a linear correlation between the magnitude of landslides and the forest cover. Many a time, man-made disturbances in a natural ecosystem may be the overriding cause of landslide hazards. The devastating landslides and associated floods of Alaknanda in 1970 have been attributed to the clearing of 6477 ha of forest land between 1959 and 1969 in the watersheds of the Patalganga, Garudganga, and Birahiganga of Chamoli districts.

DELINEATION OF SUSCEPTIBLE AREA

The landslides may cause immense damage to human life and property and untold misery to people as was seen during landslides occurring in Uttarakhand state. Much of the damages to human life, property, and developmental works can be avoided, if the likely landslide prone areas are identified and restored by the appropriate bioengineering technology on a watershed basis.

Landslide susceptibility mapping is the identification of areas within the landscape that have characteristics that could make them susceptible to landsliding.^[9] Landslide susceptibility mapping methods are diverse and numerous and often vary with the region, landscape, purpose, and finances available for the project. In the Middle and Upper Himalayan region, landslide hazard zonation (LHZ) is one technique that involves evaluation of hazard or risk caused due to slope failure processes. It considers various geo-environmental factors affecting the stability of a slope like considered land use, soil thickness, drainage, and slope condition. The LHZ mapping based on the landslide hazard elevation factor rating scheme, accepted by the Bureau of Indian Standard as an IS code, can also be used. It is a macro approach based on the basic causative factors, such as lithology, structure, slope morphology, relative relief, land use, and hydrogeological conditions. The Geological Survey of India has prepared a large number of LHZ maps of different basins in the Himalayan ecosystem.

Hardly any studies have been done for characterization and delineation of areas susceptible to mass or torrential erosion in the Lower Himalayas/Shivaliks. A study in the vertical cliff zone of the Shivalik region has been taken to develop a single-value stability indicator based on geology, physiography, and land management practices.^[10] It involved the development of a single-value stability indicator based factors that are assigned weights and normal values. Indicators have been identified at two levels, i.e., at the level of vertical cliff and at the level of strata. The sites of mass erosion-prone areas were assessed to arrive at a single value of stability based on their characteristics and strata composing them. The single value derived from this

Table 1 Giving weights to various indicators of mass erosion prone sites.

Indicator level I (properties of cliff)			Indicator level II (properties of strata)		
Parameter	Weight	Score	Parameter	Weight	Score
Number of strata	0.20	0.20			
Angle of strata	0.20	0.20			
Stability of strata	0.60		Cementation	0.60	0.36
			Clay content	0.20	0.12
			Aggregate size (MWD)	0.20	0.12
Total	1.00

assessment ranged from 0.242 to 0.934 (Table 1). On the basis of these values, sites were classified as fragile, unstable, stable, and highly stable for values of <0.40, 0.40–0.60, 0.60–0.80, and >0.80, respectively.

PREVENTIVE AND CONTROL MEASURES

State Interventions

The menace of torrents was first noticed in the middle of the 19th century, and various types of administrative, legislative, and technological control measures have been implemented. A special “Choe” (Torrent) Control Act was passed during 1902 in Punjab. Under the act, villages situated at the Himalayan foothills were evicted and goat and sheep were banned in 126 villages of the Ropar district. More than 110 Cooperative Choe Reclamation Societies were constituted to ensure people’s participation in Choe reclamation measures.

The Government of India laid major emphasis on the control of torrential erosion after independence and, with the funding by the World Bank, implemented several projects in the western part of Himalayas (Shivalik foothills) comprising the states of Punjab, Himachal Pradesh, Haryana, Jammu and Kashmir, and Uttarakhand states. The projects were christened as Kandi Watershed Area Development Project during 1980–1988, National Watershed Development Project for Rainfed Agriculture during 8th (1992–1997) and 9th (1998–2003) Five-Year Plans, and Integrated Watershed Development Project from 1990 to 2005 and 1999 to 2005.

Technological Package

The technological package includes integrated watershed management to reduce runoff and soil loss based on

the following three-pronged treatment approach: 1) catchment’s landscape measures; 2) torrent control measures; and 3) regeneration of reclaimed beds and adjoining fields. The first approach addresses the cause of the problem and is key to long-term success. The second approach addresses problems associated with the torrents and is likely to have mixed success, as it replaces natural healing processes with the need to stabilize, harden, and fix the location of channel banks to protect anthropogenic activities and infrastructures. The third approach improves the ecology and productivity of these systems and is another key to developing self-sustaining systems. Often the success of this measure will depend on the success of other approaches, the ability to manage all activities within a watershed, and whether these ecosystems have sufficient time to recover before being impacted by extreme rainfall events. A broad outline of each measure is presented in the next section together with information on the benefits of the measures.

Catchment area treatments

The measures aim to reduce runoff and soil loss and, thus, reduce the peak discharge going to the torrents. The treatments may include staggered contour trenching, terracing in the catchments, and loose stone check dams, crate wire structures, drop structures, silt retention and water harvesting structures, grade stabilizers, etc., in gullies and streams coupled with vegetative measures. Staggered contour trenching followed with vegetative measures and protection from animal grazing by local community rehabilitated the degraded catchments of Sukhna lake in Haryana. Sediment-free runoff from rehabilitated catchments can be harvested by the construction of earthen embankments. The harvested runoff not only controlled flow to the torrent but it was also recycled for sustainable agricultural production in the command area (Fig. 2).^[11]

Fig. 2 Construction of an earthen embankment at Bunga in Haryana Shivaliks stopped flash flood downstream and provided supplemental irrigation for sustainable agricultural production.

Torrent control treatments

Torrent control measures are required to control bank erosion and reclaim the area along torrent bed in excess of that needed for safe disposal of water. Spurs, gabion structures constructed transverse to river flow extending from one of the bank at an angle to the flow, are generally used to train the flow along a desired course, retain sediments around them near bank, and prevent damage to buildings, roads, etc. Based on the function served and angle to the flow direction from downstream, the spurs may be of repelling ($>90^\circ$), attracting ($<90^\circ$), or deflecting (90°) type. Repelling and deflecting spurs promote quick sedimentation on both upstream and downstream sides, but sediment is deposited only at the downstream side of attracting spurs. Construction of retaining walls to stabilize steep slopes and protect buildings on torrent banks and cross barriers to break the flow velocity are the other measures required for complete taming of torrents.

In a few studies, attracting, deflecting, and repelling type of spurs have proved effective in guiding flow and protecting banks in different locations.^[12–14] Deflecting spurs are prone to damage by scour action at their nose during heavy flow. These types of spurs require construction of aprons of larger dimension, which further enhances the cost. Vegetative reinforcement of structures/spurs proved effective in improving their efficiency and reducing the cost of treatment. Average length saved by spurs (attracting and deflecting) increased from 1.92 to 3.13 times of their length 1 year after the establishment of vegetative measures and it may improve further. Rehabilitation of the Darer Rao torrent, with 1750 ha catchment area, gave a benefit-cost ratio of 2.7:1.^[15]

Regeneration of reclaimed beds and adjoining fields

The mechanical measures in themselves are not sufficient to provide permanent solution. It is the vegetation, which offers regeneration, permanent solution, and sustainability of conservation measures for treatment of torrents. Organic matter and fertility buildup are very low in torrent beds and soil structure is almost single grained, resulting in very poor retention of water and nutrients. Among the plant species tested, shrubs of medium height proved very effective in stabilizing banks, reducing flow velocity, and promoting sedimentation.^[13] These species rehabilitated degraded lands in the torrent beds through addition of organic residues and nutrients. Fast growing multipurpose tree-based silvi-pastoral systems provide ample returns to the farmers besides rejuvenating the torrent beds.

CONCLUSION

The post-independence era (1947 onwards) of India has witnessed the rapid expansion of areas prone to torrential

erosion because of deforestation, increased biotic pressure, and construction activities in the Himalayan hills; 2.73 Mha area is affected by torrential erosion in the Indian Himalayas alone. These areas experience soil loss up to $550 \text{ Mg ha}^{-1} \text{ yr}^{-1}$ in mine spoiled hills and runoff up to 65% of monsoon rains causing flash floods and sand deposition in the fields. The areas vulnerable to torrential erosion can be delineated using geo-environmental factors in Upper and Middle Himalayas and single-value stability indicator in Lower Himalayas/Shivaliks. Technology package for control of torrential erosion comprising suitable soil conservation measures for denuded catchments and shallow streams has proved effective in checking the torrential erosion and regeneration of degraded lands. These measures have shown a marked reduction in runoff and soil loss.
